A. Three models: Comparison

The paper compares the empirical performances of two models: one with only ad-valorem costs (Model (A)) and one with where both ad-valorem and additive costs (Model (B)). For comparison purposes, we also estimate a third model with only additive costs (Model (C)), in which case the estimated equation is:

$$\ln \left(\frac{p_{ik}}{\tilde{p}_{ik}} - 1 \right) = \ln \left(\frac{t_i + t_{s(k)}}{\tilde{p}_{ik}} \right) + \epsilon_{ik}^{add}$$

In this section, we first compare the estimates of the transport costs components under the three models. In a second step, we report quality of fit tests for the three models.

A.1. Estimation results

We report estimations of the three models for selected years. Section C provides estimations for every year. Table A.1 reports the results for air transport, Table A.2 for vessel transport.

Statistics are weighted by value

Model (A): Ad-valorem transport costs only**Model (B): With additive and ad-valorem transport costs****Model (C): With additive transport costs only**

as in Models (A) and (B). We also observe a downward trend of transport costs over time, in particular since 1980.

A.2. Quality of fit diagnostic tests

To go further into the comparison of the empirical relevance of our three empirical models, we compare quality of fit diagnostic tests. Table A.3 reports the results for air transport, and Table A.4 those for vessel transport. In both tables, we report the values of the R^2 , the Standard Error of Regression (SER), the AIC criterion and the log-likelihood (LL) value. We also report the value of the log-likelihood ratio that tests the quality of fit of the global model (Model (B)) compared to the other two models.

Table A.3: Quality-of-fit diagnostic tests, Air, 3-digit level

SER are weighted by value

Model (A): Ad-valorem transport costs only

Model (B): With additive and ad-valorem transport costs

Model (C): With additive transport costs only

For all years and whatever the transport mode considered, the model with additive costs only (Model (C)) is consistently dominated (in terms of quality of fit properties) by the model with multiplicative costs only (Model (A)), which is itself consistently dominated by the complete model (Model (B)). This conclusion holds whatever the type of diagnostic test considered. That justifies our choice to disregard Model (C) in the main text.

Model (C): With additive transport costs only

B. Estimation at the 4-digit level

In this section, we report the estimation results when we retain a sectorial classification at the 4-digit level ($s=4$ -digit).

B.1. Transport cost estimates

Tables B.1 and B.2 report the estimates of both models (with and without additive costs) in air and vessel transport respectively. Estimates at the 4-digit level confirm the significant role of the additive component in fitting international transport costs that we found at the 3-digit level.

B.2. Goodness-of-fit tests at the 4-digit level

We now report the goodness-of-fit exercise (conducted by transport mode) at the 4-digit product classification level (for the selected years). The results are reported in Tables B.3 (for air) and B.4 (for vessel).

If anything, the quality of fit appears slightly higher when estimations are based on the 4-digit classification. This is especially true for the model restricting transport cost to their ad-valorem dimension, whatever the transport mode considered. When the additive part is taken into account however, the difference in goodness of fit between the 3- and the 4-digit classification level becomes very small, whatever the considered criterion. Using a more disaggregated product classification unsurprisingly adds some statistical precision, but the gain is not large enough to disqualify the use of slightly more aggregated data.

Table B.1: Air: Transport costs estimates, selected years, 4-digit level

| # of restrictions | 797.0 | 853.0 | 913.0 | 882.0 | 884.0 |
| p-value | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 |

Notes: Model (A) = with only ad-valorem transport costs. Model (B) = with additive & ad-valorem transport costs. R^2 between the log of predicted ratio and the log of the observed ratio. The number # of restrictions is equal to the number of parameters estimated, i.e. the number of partner countries plus the number of sectors.

C. Transport Cost Estimates: Yearly Detailed Results

In this section, we complement Table 1 of the main text by reporting the year-to-year results of the estimation driven at the 3-digit classification level. Table C.1 reports the results for each year over 1974-2019 for vessel; Table C.2 reports similar results for air transport. In both cases, we report the estimated values of the transport costs (weighted mean and median) when only ad-valorem costs are modeled (Model (A)), when both additive and ad-valorem costs are modeled (Model (B)) and when only additive costs are modeled (Model (C)). In all tables, statistics are weighted by value.

As it can be inferred from Table C.2, the estimates for air transport costs in 1989 show a surprisingly high value for the additive component (the additive cost is estimated to amount to 4.6% of the export price, whereas it amounts to 2.5% on average between 1974 and 1988, and to 1.7% over the following decade 1990-2000). This can be attributed to the presence of outliers in the distribution of the additive costs estimates, despite the exclusion of outliers in the data. The maximum value for \hat{t}/\tilde{p} is 10,000% in 1989, whereas it amounts to 1,690% on average over 1974-1988 and to 1,500% on average over 1990-2000. Accordingly, in the paper we discard this year 1989 when we report the average values over the period of the transport costs estimates in air transport, all the more as excluding or not excluding a single year out of 45 ones does not make much difference in the weighted mean transport cost.

D. Robustness checks

D.1. Variance decomposition exercise

In this section, we provide a variance decomposition exercise on the observed cif-fas price gap. Specifically, we determine the share of the observed variance in the ratio $\ln(\frac{p_{ik}}{p_{ik}} - 1)$ that comes from *i*) the between-product variance (at the 5-digit level, k) and *ii*) the between-sector variance (at the 3-digit level, s). The variance decomposition expression at the product level k is obtained by applying the following formula (by year and transport mode):

$$\sum_{k=1}^K \sum_{i=1}^I (x_{ik} - \bar{x}_g)^2 = \underbrace{\sum_k \sum_i (x_{ik} - \bar{x}_k)^2}_{(1)} + \underbrace{\sum_k (\bar{x}_k - \bar{x}_g)^2}_{(2)}$$

with x the observed cif-fas price gap and \bar{x}_g, \bar{x}_k average values defined as:

$$\bar{x}_g \equiv \frac{1}{n} \sum_{k=1}^K \sum_{i=1}^I x_{ik}, \quad \bar{x}_k \equiv \frac{1}{K} \sum_{i=1}^I x_{ik}$$

with n the total number of observations, K the total number of products and I the total number of country partners. In the above equation, the left-hand side gives the total variability, which decomposes into the within-product variability (Term (1)) and the between-product variability (Term (2)). We apply the same variance decomposition exercise at the sector level, in which case the sector s index (at the 3-digit level) replaces the k index (at the 5-digit level). This gives us an alternative way to ensure the robustness of the estimation results to the precision of the sector classification retained to estimate international transport costs. We also determine the share of the observed variance that can be attributed to the between-country variance, adapting the variance decomposition formula written above accordingly. Results are reported in Figure D.1.

Figure D.1: Variance decomposition (observed cif-fas price gap)

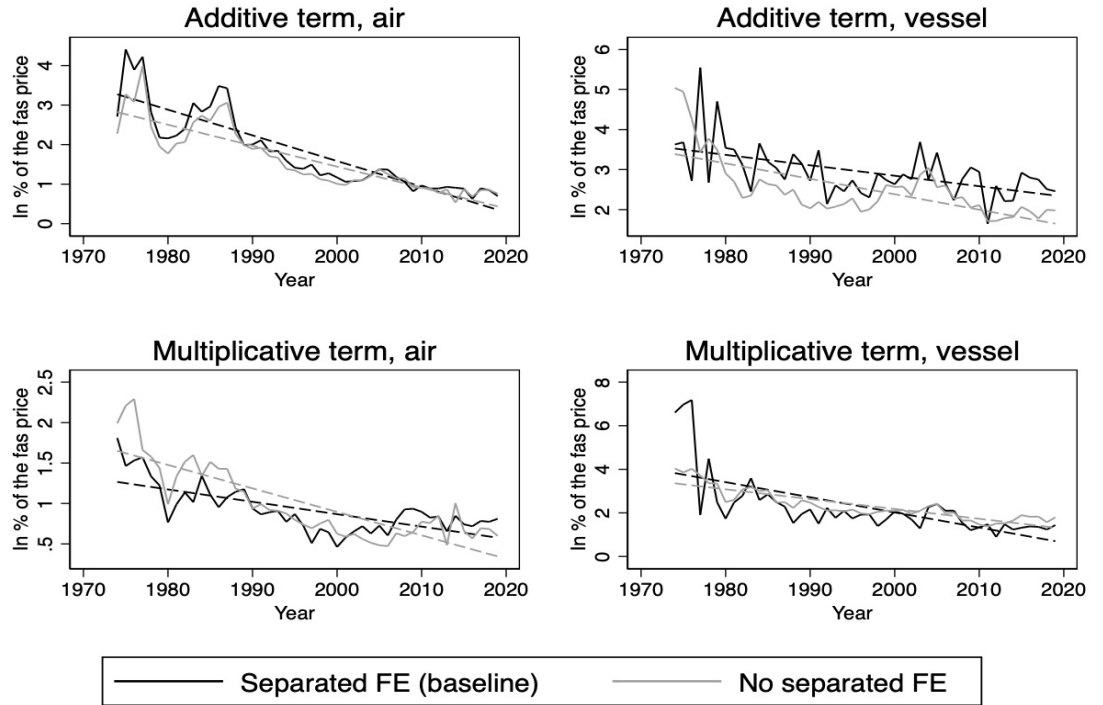

Two interesting results emerge from Figure D.1. First, the share of the cif-fas price gap variance that comes from the variance between products (5-digit level) is close to the variance between sectors at the 3-digit level. Both account for between 30 and 40% of the total variance in air transport, depending on the years considered. This is also the case for vessel transport, even if the difference between the between-product variance share and the between-sector share is larger (30% for the between-sector vs 40% for the between-product variance at the beginning of the period). This suggests our procedure should be robust to the choice of the precision of the sector classification. Second, the variance of the cif-fas price gap that can be attributed to the product (or sector) dimension is much larger than

the between-country variance. This holds throughout the period and for both transport modes.

D.2. Separability Assumption

In this section, we report more results on the separability assumption robustness check. Figure D.2 displays the results on a yearly basis for air transport in panel (A) and for vessel transport in panel (B). In each case, the estimated values (as well as the regression line) under both separability (baseline) and non-separability are reported, for the additive term (upper panel) and the ad-valorem term (lower panel).

Figure D.2: Robustness to the separability assumption (year-to-year basis)

Notes: FE for (country, sector) fixed effects.

In line with Table 2 of the paper, Figure D.2 confirms that the separability assumption (retained in our baseline estimation) tends to overestimate the value of the additive cost component (and underestimate the value of the ad-valorem cost). However, it also shows that the difference is quantitatively small in most cases. Further, and most importantly, whatever the transport mode and for both types of transport costs, the trends, whether estimated under the separability assumption or not, are very similar. This confirms the robustness of our estimation results to this assumption.

D.3. Estimating $\hat{\beta}_{i,s}$ directly

In this section, we explore an alternative estimation method (so called “direct method” for sake of clarity), which proceeds as follows. β can be separately estimated for each sector s -origin country i using the following regression:

$$\ln TC_{ikd} = \beta_{is} \ln \tilde{p}_{ikd} + Z_{ikd} + \epsilon_{ikd} \quad (1)$$

where d denotes the US district of entry and k denotes an HS-10 product, TC_{ikd} being the transport costs and Z a set of controls variables. The identification of β_{is} , in this case, relies on exploiting the variability between products at the 10-digit level (k) and between ports of entry in the US (d). From this, one can then recover the levels of additive and multiplicative transports costs. Denoting $\hat{\beta}_{is(k)}$ the estimated β for a given sector-country $i, s(k)$, one can indeed solve the following two-equation system:

$$\begin{aligned} p_{ik} &= \tau_{is(k)} \tilde{p}_{ik} + t_{is(k)} \\ \frac{t_{is(k)}}{(\tau_{is(k)} - 1) \tilde{p}_{ik} + t_{is(k)}} &= \hat{\beta}_{is(k)} \end{aligned}$$

with p_{ik} and \tilde{p}_{ik} the cif and fas prices observed in our dataset (conditional on a given year-transport mode).

One advantage of this approach is that the above equation is linear and can be estimated separately for various country-industry pairs, without having to resort on the separability assumption. Actually, it still requires a non-linear estimator due to the necessity of imposing an *ex-ante* restriction on parameters, i.e. imposing $0 \leq \beta \leq 1$. Should we relax this restriction, standard linear, least squares estimates often deliver negative, meaningless estimates. In this respect, the requirement of resorting on non-linear estimates (and the computational, time-consuming burden it induces) remains.

This estimation method also implies a lower coverage, both in time and in the sectors/countries covered. With respect to time coverage, information about the port of entry is only available since 1989, which is already smaller than our full sample starting in 1974. On top of that, because of the Covid situation, the US Bureau of Census was only able to provide us the data for the years 1997-1999 and 2001-2019. Using it would hence reduce the time coverage of our analysis by more than 20 years (skipping the 1974-1996 years in particular). In our view, the historical coverage is interesting *per se*: it provides useful insights about how transport costs have evolved over several decades and more importantly, it allows us to highlight the welfare alterations induced over the “hyper-globalization” period by the relative dynamics of additive and multiplicative costs.

With respect to the trade flows coverage, the method is run country by country, and 3-digit sector by 3-digit sector, exploiting the variability within each country-3d sector across 10-d sub-sectors and ports of entry. Yet, it appears that for many pairs (country, 3-digit sector), there is too few variability across sub-sectors or ports en entry given the number of fixed effects included in the regression, to estimate the equation. This can be seen comparing the number of observations by year/ transport mode between this alternative method and our baseline method reported in Table D.1. Put differently, this methodology discards countries which export a limited range of goods to the US and/or which arrive in the USA through the same ports of entry. In this respect, the induced selection bias reduces the general scope of the transport costs estimates.

Notwithstanding these limitations, it remains interesting to run this alternative estimation method as robustness check. Table D.1 reports the estimation results, by transport mode, in the Column “Alternative”, along with the results obtained with our baseline method over the same period 2005-2013. Figure D.3 displays the estimated share of additive costs β on a yearly basis over the estimation period, under both methods.

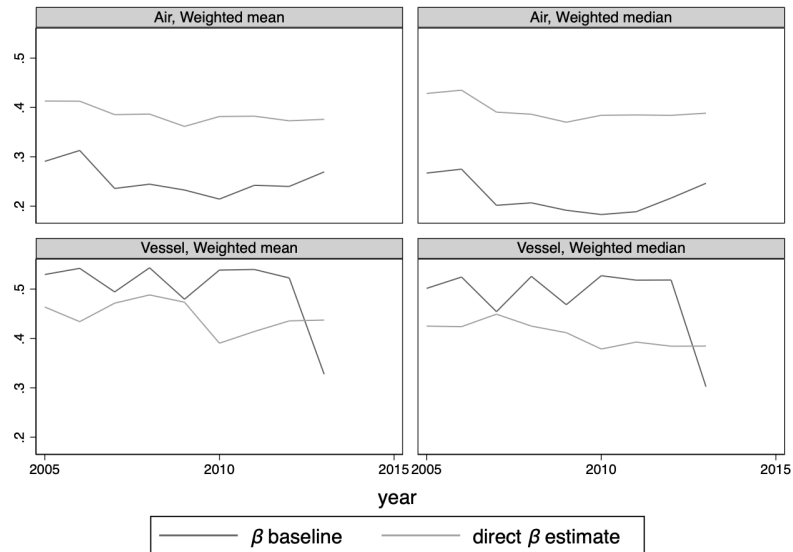

As noted above, the number of partners-sectors covered are lower. Regarding the share

Table D.1: Baseline and direct β estimate, 2005-2013

| Transport mode | Air | | Vessel | |
|---------------------------------|-------------|----------|-------------|----------|
| Estimation method | Alternative | Baseline | Alternative | Baseline |
| Coverage | | | | |
| Nb sectors | 177 | 217 | 203 | 227 |
| Nb partners | 112 | 210 | 123 | 204 |
| Nb pairs | 3,872 | 12,158 | 3,743 | 12,440 |
| Annual covered value (Bn USD) | 262 | 293 | 824 | 906 |
| Share of additive costs β | | | | |
| Mean | 0.39 | 0.25 | 0.45 | 0.50 |
| Median | 0.39 | 0.22 | 0.41 | 0.48 |
| Std. dev. | 0.15 | 0.19 | 0.29 | 0.28 |
| Time trend coefficient | -0.012 | -0.020 | -0.012 | -0.031 |

Notes: Time trend coefficient is the annual growth rate.

of additive costs β , the comparison between the two methods delivers opposite conclusions depending on the transport mode. While the estimated β is lower for vessel transport with the alternative method (also displaying a larger decrease over the period), the opposite holds for Air transport. In any case, the share of additive costs remains substantial, around 40% on average across transport modes over the period, thereby confirming the main message of our paper regarding the importance of the additive component in international transport costs.

Figure D.3: Baseline and direct β estimate

If we take the value of β by itself, there is no clear criteria to discriminate between the value estimated with the baseline method and estimating directly β (when, of course, run on the same sample). Further, as shown in Table D.1, there is no clear sign of a potential

upwards or downwards bias that would be attached to either method.

Things are more clear-cut in terms of accuracy of the estimation. Specifically, we show that the baseline method yields a more precise estimation of the β than the direct method. We reach this conclusion by implementing the following steps, for each year and transport mode.

- The direct method estimates one value for the share of additive component β at the i, s level denoted $\hat{\beta}_{is(k)}^{dir}$ associated with a standard deviation SD_{is} , by year and transport mode (where the subscript dir identifies the direct method). From this, we can compute the size of the 5-95% confidence interval $CI_{is}^{dir} = \hat{\beta}_{is}^{max,dir} - \hat{\beta}_{is}^{min,dir}$ where:

$$\hat{\beta}_{is}^{min,dir} = \hat{\beta}_{is(k)}^{dir} - 1.96SD_{is}, \quad \hat{\beta}_{is}^{max,dir} = \hat{\beta}_{is(k)}^{dir} + 1.96SD_{is}$$

- The baseline method estimates the underlying trade costs components $(\hat{\tau}_i, \hat{\tau}_s, \hat{t}_i, \hat{t}_s)$ with an associated matrix of variance-covariance, from which we can rebuild β_{is} (on a year-transport mode basis). As such, it does not yield an estimate of β_{is} and an associated standard deviation, so that we cannot directly compare the precision of the estimation. We hence compute the accuracy of the β estimation through a bootstrap method. Specifically, on a yearly/mode basis we draw a distribution of transport costs components and associated β_{is} (10,000 random draws) from which we can compute the mean, the median and the 5-95 confidence interval for each couple i, s . Denoting β_{is}^{95} and β_{is}^{05} the associated thresholds, we then obtain the size of the confidence interval $CI_{is} = \beta_{is}^{95} - \beta_{is}^{05}$.¹
- We can then evaluate the accuracy of each method by comparing the size of the confidence intervals of the β , for each couple i, s (by year and transport mode). We summarize this comparison in Figure D.4, which reports the distribution of the ratio of confidence intervals, taken in log.

In most cases, the log of the ratio is negative, implying a smaller interval confidence of the baseline β estimation. Our method thus yields more accurate estimations of the share of additive components, whatever the transport mode considered. We have checked that a similar conclusion applies on other years (they are not reported here for sake of brevity but they are available upon request).

One explanation of the limited accuracy of the alternative method might be the following. Given that the estimation method is run at the country-sector level (exploiting heterogeneity *within* a given country-sector pair), it implicitly assumes that transport costs are independent *across* sectors and *across* origin countries. Put in plain words, it assumes that transport costs of say, cars, have nothing in common whether those goods come from France or from Germany; or that transport costs that apply to imported goods from France have no common component across sectors. This is a disputable assumption. From a statistical point of view, it implies leaving aside information contained in the fact that transport costs have a both a country-specific component and a sector-specific component. We believe that this explains the better accuracy of our baseline estimation.

¹Notice that this should be made on the same sample as the one obtained with the direct method, since the goal is to compare the accuracy of the β_{is} estimate - implying to have the same sample of countries / sectors at first.

Figure D.4: Accuracy of the estimation of the β : Comparison

Note: Ratio of the confidence intervals = $\ln(CI_{is}/CI_{is}^{ref})$

D.4. Weights and quantities

In the baseline method (as in most of the literature), the explained variable is a per-kg price rather than an unit price. [Lashkaripour \(2020\)](#) notably points out the importance of this issue. Based on US data very similar to ours over the period 1995-2015, the paper highlights, among other results, that the unit weight of imported goods is substantially heterogeneous even within narrowly-defined product categories and the cost of transportation increases more rapidly with unit weight than with the cost of production. [Lashkaripour \(2020\)](#) finds that accounting for the heterogeneity in export unit weights provides evidence in favor of the ad-valorem cost assumption regarding transport costs. This result of transport costs close to be totally ad-valorem contrasts from our own findings of additive costs representing 30 to 45% of total costs. There are explanations for this difference. Beyond a longer time span, our database is exhaustive, and encompasses all goods and industries, while [Lashkaripour \(2020\)](#) restricts to indivisible/discrete goods that represent a bit more than 56% of US total imports of goods in his dataset. In this regard, when comparing Tables 1 and 10 in [Lashkaripour \(2020\)](#), one can see that the share of multiplicative costs tends to decrease with the share of discrete goods. It is therefore reasonable to think that the inclusion of all goods, like in our setting, would move the average share of multiplicative costs far from 100%.

Nevertheless, this section investigates the robustness of our results when unit values are built as the ratio between value and quantity of goods per observation. We first discuss data and estimation difficulties before giving the results. At a more fundamental level, we argue that looking at transport costs on a per-weight basis does add relevant information.

Data availability issue. The first difficulty is availability of information on quantities. Neither the US Bureau of Census data nor the 1974-2004 Hummels's data (based on the Census Bureau data) report the quantity by transport mode. This is incompatible with our empirical strategy for estimation which is conditional on the transport mode, similarly as in [Hummels \(2007\)](#). As a result, computing the unit price of all trade flows would

require the assumption that the weight per unit is the same for vessel shipments and air shipments at the level of the observation. This is unlikely, as one would expect the higher value-to-weight varieties to be transported by air rather than by vessel. The alternative is to consider only single-mode flows. In Hummels’s data (1974-2014), on average 41.1 % of trade flows and 79% of trade value are multi-mode. Reducing the total value of the sample from 12,500 billion dollars to 2,650 billion dollars would entail a large loss of useful information. Original census data, when accessible, are more promising.² In 2019, multi-modal flows are 570 billion dollars out of 1,790 billion dollars, or 31% of the data. This is still a large share, but not too large to preclude any work. Accordingly, we dig deeper into this issue with the US Census dataset, restricting to single transport mode flows.

Quantity units are a second difficulty. The Census data remain silent on that matter. To the best of our knowledge, these can only be found in the “Harmonized Tariff Schedule of the United State”. Unfortunately, these schedules change many time per year and only the schedules from 2009 onwards were available in a .csv format. On the years for which the match could be done (from 2009), it turns out that at our sector level (3-digit), goods (either at the 5-digit or the 10-digit level) are measured in different units. In 2019, only 125 3-digit sectors out of 230 are measured in a single unit (after cleaning up the unit names³).⁴ Neglecting these differences would invalidate our functional forms, as no one expects the transport cost of a “piece” to be the same as the transport cost of a “kg”, even in the same sector. So we are limited to using quantity units from 2009 to 2019, amending our structure of fixed effects to consider the triplet (origin country, sector, quantity unit).

Estimation issue. Getting deeper on the estimated functional form raised another difficulty in adapting our equation to per-unit rather than per-weight price. As discussed above, in our baseline regression we separate each transport cost component in two distinct sector-country dimensions. As in Irarrazabal et al. (2015), we assume an additive form for the additive cost, i.e. $t_{is(k)} = t_i + t_{s(k)}$ with i the origin country and s the sector. In the specific case of quantities, this raises a non-trivial issue for country-level fixed effects. Sector-level fixed effects could indeed be easily replaced by (sector \times quantity unit) fixed effects; but the same does not appear possible for country fixed effects. Let us elaborate on this issue.

In the per-weight price, the existence of a single country fixed effect applicable to all sector could be justified, as a kilogram is always a kilogram and one can assume they both add the same to transport costs from, say, Germany. In contrast, an unit of tee-shirt is quite different from an unit of car. To clarify this point, consider imports of tee-shirts and cars from Germany and China. Under the separability assumption, importing a tee-shirt from either country implies paying the cost given by the country fixed effect (the same for all sectors) plus the cost given by the sector fixed effect; and similarly for importing

²Original Census data are reported at the HS-10 digit \times district of entry \times district of unloading \times rate provision code.

³As units are not always coherent (e.g. weight can be given in “kg”, “kg.” “Kg” and, also, “g” and “t”).

⁴For instance, 3-digit SITC sector “061 Sugar, molasses and honey” includes among other products, 5-digit SITC product “6150 Molasses, whether or not decolourized”, measured in liters and 5-digit SITC product “06160 Natural Honey” measured in kg. Even worse, the 5-digit SITC product “06190 Other sugars; sugar syrups; artificial honey (whether or not mixed with natural honey); caramel” includes both 10-digit HTS product “1702903500 Other: invert molasses”, measured in liters and 10-digit HTS product “1702602200 Blended syrups described in additional u.s. note 4 to chapter 17: described in general note 15 of the tariff schedule and entered pursuant to its provisions” measured in kilograms.

a car. Hence, the difference in the cost of importing a car from Germany versus China would be the same, in dollars, as the difference between the cost of importing a tee-shirt from Germany relative to China. This does not seem a sensible assumption. In this setting, we cannot keep the separability assumption. As discussed before, this dramatically increases the computational difficulty of our method (with no substantial different results, see Subsection 3.3.1. in the main paper).

Integrating these various constraints, we run the robustness check (weight versus quantity) *i)* on a sample reduced over 2009-2019, considering single transport mode flows - amounting to 66% of the value of the baseline sample; *ii)* retaining a non-separable structure of three-dimensional fixed effects $t_{is(k)u}$, $\tau_{is(k)u}$ according to the following equation:

$$\ln \left(\frac{p_{iku}}{\tilde{p}_{iku}} - 1 \right) = \ln \left(\tau_{is(k)u} - 1 + \frac{t_{is(k)u}}{\tilde{p}_{iku}} \right) + \epsilon_{iku}$$

where p_{iku} refers to the cif price associated with quantity of goof k imported from country i , measured in unit u (e.g. kg or number), \tilde{p}_{iku} the corresponding unit value (fas price).

The results are reported in Table D.2 and in Figure D.5. In Table D.2, for each transport mode, the first column reports the estimation based on the price per quantity; while the second column reports the results obtained considering the price per kg on the same sample; the last column reported our baseline results on the large sample (considering the average value over 2005-2019, under the separability assumption).

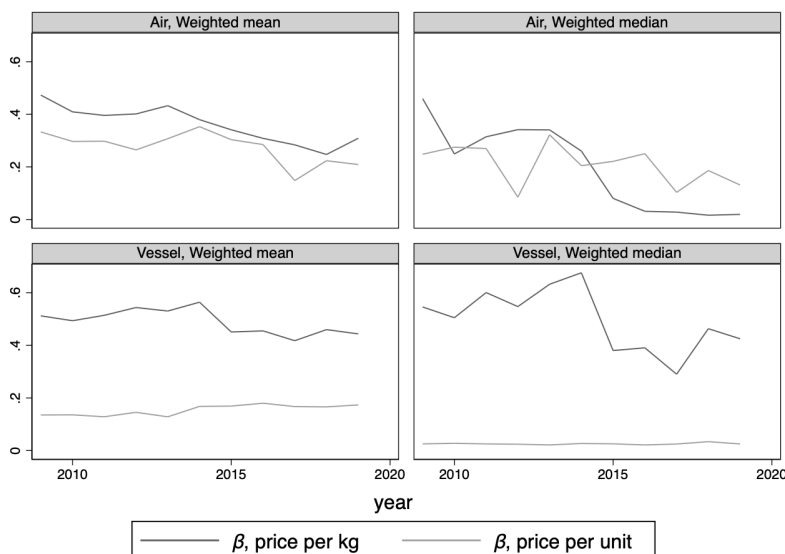

Table D.2: Comparison Price per quantity or Price per kg, 2009-2019

| Mode: | Air | | | Vessel | | |
|---------------------------------|---------|---------|----------|---------|---------|----------|
| Price per: | Qy | Kg | Kg | Qy | Kg | Kg |
| Sample | Limited | Limited | Baseline | Limited | Limited | Baseline |
| # of sectors | 22 | 22 | 216 | 60 | 60 | 225 |
| # of partners | 15 | 15 | 211 | 21 | 21 | 205 |
| # of pairs | 339 | 339 | 12,544 | 1,100 | 1,100 | 12,649 |
| Trade value (Bn USD) | 242 | 242 | 331 | 583 | 583 | 920 |
| Share of additive costs β | | | | | | |
| Mean | 0.27 | 0.36 | 0.22 | 0.15 | 0.49 | 0.45 |
| Median | 0.19 | 0.16 | 0.17 | 0.03 | 0.51 | 0.44 |
| Std. dev. | 0.29 | 0.39 | 0.19 | 0.25 | 0.29 | 0.26 |
| Time trend coefficient | -0.049 | -0.054 | -0.026 | 0.032 | -0.020 | -0.022 |

Two main results emerge. First, given the constraints on the sample selection for quantities, the estimation based on quantity can only be run on a reduced sample. In contrast to the aggregation and the separability issues, these restrictions strongly limit both the number of sectors and of countries covered, and do also impact the value of trade flows covered. This raises a non-trivial sample selection bias that would limit the general scope of our transport costs estimates.

Second, in terms of β estimates, the results clearly show that using price per unit (whatever that unit is) instead of price per weight decreases the share of additive costs (except if one look at the median for air). In this respect, they stand in line with the results of Lashkaripour (2020), and confirm the correlation between weight per unit and unit price. Still, the share of additive cost is not reduced to zero (except if one looks at

Figure D.5: β Estimate: Price per quantity or price per kg, 2009-2019

Notes: In both cases, estimation is run without imposing the separability assumption.

the median for vessel). Thus these results do not disqualify our approach, especially as we cover a much larger period and sample with our baseline estimate.

On the relevance of the per-weight price approach. At a more fundamental level, we do believe that the study of transport costs measured on a per-weight price adds some relevant information on the international transport cost burden faced by exporters. We detail below why.

Our main objective in this paper is to provide a quantitative assessment of the international transport costs burden over time; on that matter, one may start with the observation that transport cost schedules are expressed through a mixed per-weight and per-volume basis, both historically and nowadays. For example, in 2021, air freight trade costs are expressed in weights, with a minimal weight per volume (“volumetric weight” or “dimensional weight”)⁵ while maritime freight costs are expressed in volume. Hence, looking at per-kg transport cost can be interpreted straightforwardly as trying to estimate the actual existing shipping costs, with sector fixed effects interpretable as measures of mean density for different sectors. The existence of per-volume or per-weight shipping cost is directly linked to the technical constraints of the transportation sector, hence exogenous to exporting firms’ decisions - in contrast, per-unit shipping cost depends on the behavior of exporting firms. Put differently, the shipping cost per weight is one of the exogenous parameters firms take into account in their production choices, including weight per unit. Accordingly, studying the technical per-volume or per-weight shipping cost is interesting to understand the context in which they operate.

In a related manner, restricting the sample to denumerable goods would defeat our

⁵See for example <https://transporteca.co.uk/shipping-costs>, <http://wap.dhl.com/serv/volweight.html> and https://en.wikipedia.org/wiki/Dimensional_weight.

purpose of estimating international transport costs for the whole range of US imports. This is illustrated in Figure D.6. After computing the share of discrete goods per 5-digit SITC import in 2009, we have used the changing composition of US imports to approximate the share of discrete goods in the total value of US imports on a yearly basis. According to this rough approximation, discrete goods are between 23% and 52% of US imports, reaching a value only above 50% for two years. Switching to a per-unit approach would hence mean a marked reduction in the trade flows coverage, thereby limiting the general scope of our estimates.

Figure D.6: Estimated share of discrete goods in US imports, 1974-2019

E. Eliminating the composition effects

E.1. More on the Hummels' methodology

This section complements Section 4 in the main paper, where we replicate the method adopted by Hummels (2007) on our database. Here, we report the raw measure of transport costs versus the “ceteris paribus” transport costs series, i.e. excluding composition effects, in percentage of the export price, as in Hummels (2007), for each transport mode. The parallel with Hummels’s (2007) terminology stands as follows: In Figure E.1, the “transport costs, excluding composition effects” series refers to his “fitted ad-valorem rate”; the “raw transport costs” series refers to his “expenditure/import value”. Unsurprisingly, this accords with his Figure 5 (for Air) and 6 (Vessel) for the same period (until 2014).

E.2. Composition effects: Primary vs. Manufacturing sector

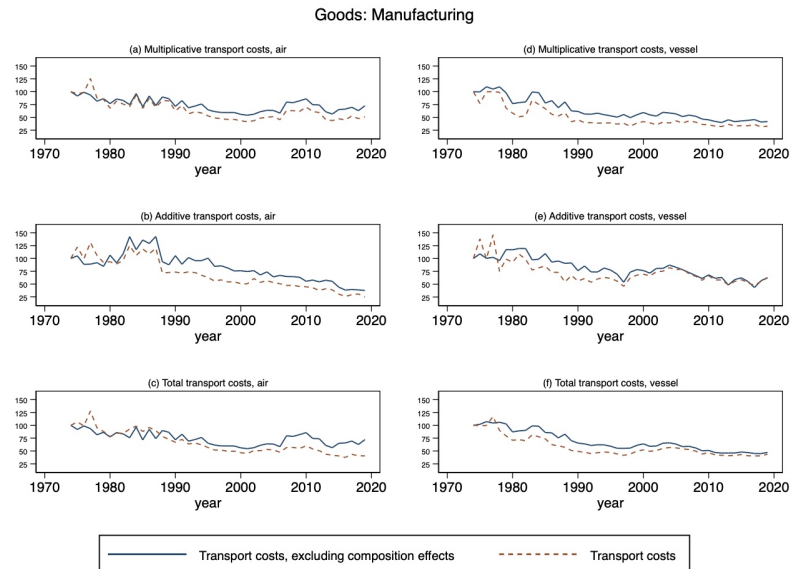

In this section, we refine the characterization of the evolution of international transport costs by distinguishing primary and manufactured goods trade flows. The evolution in transport costs over time, by transport mode (overall transport costs and composition effects excluded) is reported in Figure E.2 for the manufacturing sector, and in Figure E.3 for the primary sector. To ease the comparison, we also report the results obtained on the whole range of trade flows (i.e., Figure 2 of the paper), in Figure E.4.

Figure E.1: Characterizing the time trends: applying Hummels's (2007) method

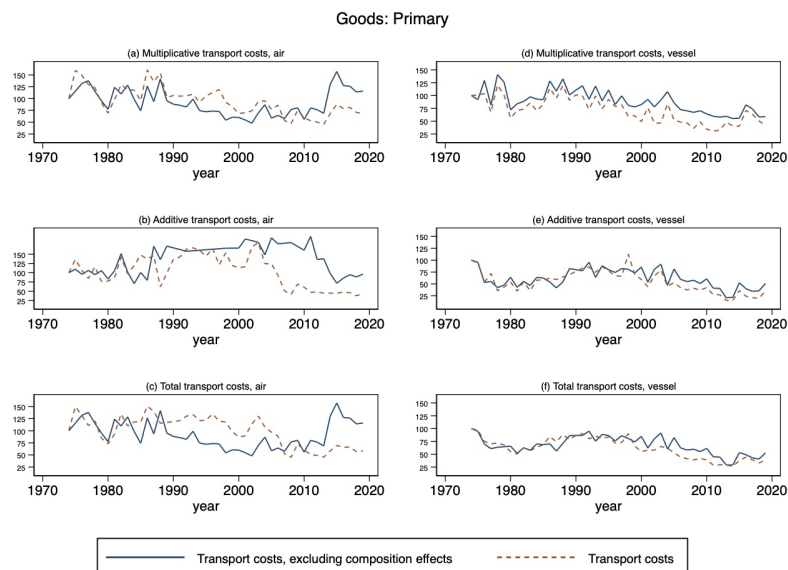

The classification retained to categorize trade flows follows the UNCTAD classification (on SITC Revision 3)⁶. “Primary goods” flows are recorded as “Food and live animals” (First digit “0” in the SITC Classification), “Beverages and tobacco” (First digit “1”), “Crude materials, inedible, except fuels” (First digit “2”), “Mineral fuels, lubricants and related materials” (First digit “3”), “Animal and vegetable oils, fats and waxes” (First digit “4”), “Pearls, precious & semi-precious stones” (Classified “667” in the SITC Classification) and “Non-ferrous metals” (classified “68” in the SITC Classification). All the other flows are part of “Manufacturing”.

Figure E.2: Transport costs (with and without composition effects), Manufacturing

⁶See “UNCTAD product groupings and composition (SITC Rev. 3)” in <http://unctadstat.unctad.org/EN/Classifications.html>, accessed Septembre 2018

Figure E.3: Transport costs (with and without composition effects), Primary goods

As reported in Figures E.2 and E.3, both the “pure” transport costs and the raw measure have regularly declined over the period in both sectors, by roughly the same order of magnitude (50% in air, 60% in vessel for overall transport costs, panels (c) and (f)). However the role of trade composition effects in accounting for this trend depends on the sector.

In the manufacturing sector, Figure E.2 reports a very similar time trend decomposition than what is obtained on the whole range of goods (Figure E.4). One can further notice that in vessel transport, composition effects play virtually no role at the end of the period, as most of the decrease can be imputed to the reduction of “pure” transport costs (the blue continuous line)

The situation is different in the primary sector. In air transport, the role of composition effects exhibits an irregular pattern over time. They dampen the reduction in pure transport costs up to the 2000s. Afterwards, they conversely more than compensate the increase in pure transport costs (Figure E.3, left-hand panels (a), (b) and (c)). In vessel transport, the composition effects play a limited role in the primary sector, similarly to their role for the whole range of goods (Figure E.3, right-hand panels (d), (e) and (f)), by slightly amplifying the reduction in the pure transport costs.

One explanation for the similarity between the results for the manufacturing goods trade and for total trade can be found in the share of primary goods in total flows as reported in Figure E.5. In air transport, the share of primary goods in the total value of US imports is very small, around 10%. Primary goods make a higher proportion of trade flows in vessel transport, especially over 1974-1982 (between 40% and 60%). On the following sub-period though, their share has fallen to 20-30%. Given the modest proportion of primary goods in total import flows of the US economy compared to the manufactured goods, it is not surprising that the diagnosis made about the time trend of transport costs when all types of flows are considered is driven by the manufacturing.
