

INTERNATIONAL TRANSPORT COSTS: NEW FINDINGS FROM MODELING ADDITIVE COSTS*

Guillaume DAUDIN[†] Jérôme HÉRICOURT[‡] Lise PATUREAU[§]

February 2018

Abstract

This paper provides a quantitative assessment of the size and the importance of the additive component in international transport costs. To do so, we exploit information contained in the US imports flows database over 1974-2013, distinguishing by transport mode, air and vessel. Two main new findings emerge. First, the additive component of transport costs is sizeable, with mean values over the period of 1.8% and 2.9% of the export price in air and vessel transport respectively. Second, and in contrast to Hummels (2007), we find that composition effects play a minor role in accounting for the reduction of transport costs relative to the value of US imports. Transport cost “per se” did decline. Importantly, this difference of results can be attributed to the new way of modeling the additive component of transport costs we offer.

1 Introduction

Trade costs are central to international economic analysis. In particular, they are considered a major obstacle to international economic integration and international trade flows. According to Jacks *et al.* (2008), the trade cost decline explains around 55% of the pre-World War I trade boom and 33% of the post-World War II trade boom, while the abrupt rise in trade costs explains the inter-war trade collapse. After 1950, average trade costs fell by 16%, notably through the reduction of policy trade costs promoted through the GATT (WTO after 1995) multilateral agreements. Based on panel data, Novy (2013) finds that U.S. trade costs with major trading partners declined on average by about 40 percent between 1970 and 2000. Yet, several papers (mostly based on empirical estimates of the gravity equation) have shown that trade costs still remain a major obstacle to trade (Head and Mayer, 2004 and Disdier and Head, 2008). Using data over 1989-2000, Anderson and Van Wincoop (2004) thus estimate that average international trade costs for industrialized countries represent a 74% markup over production costs.

Defined as the costs associated with the exchange of goods across national borders, trade costs are usually split between transaction costs (information costs, contract enforcement costs, costs associated with the use of different currencies...), policy costs (tariff and non-tariff costs), time costs (time to ship goods) and transport costs *per se*. In this vein, Anderson and Van Wincoop (2004) obtain that around 30% of international trade costs are attributable to transport costs. Equivalently, international transportation costs would represent a 21% markup over production costs. Further, the sizeable elasticity of trade with respect to freight costs obtained by Behar and Venables (2011) (around -3) suggests a non-negligible impact of transport costs on trade flows. If much of trade policy barriers have been removed over the second half of the 20th century, these findings point out that the transport costs component of the overall trade costs remain large and deserve attention. International transport costs accordingly stand at the heart of the paper.

This focus is shared with part of the international trade literature that studies the patterns of transport costs over time, such as Hummels (2007) and Behar and Venables (2011). Many argue that transport costs have substantially decreased with technological advance in transportation, infrastructure development and new communication technologies (see Lafourcade and Thisse, 2011). Glaeser and Kohlhase (2004) find that, over the twentieth century, the cost of moving goods have declined by over 90% in real terms. However, Hummels (2007) points out that trade composition effects dominate the characterization of time trends of international transport costs and that transport costs “*per se*” (i.e., *ceteris paribus* for given goods and origins) have not declined much. In this paper, we investigate the robustness of this result. As major contribution of the paper, we find that composition effects play a minor role in accounting for the trend patterns of transport costs, in contrast to Hummels (2007). Importantly, we show that this difference of result can be accounted for by the modelling of the additive component of international transport costs (i.e., a transport cost per unit traded). Once we allow for a more flexible (and empirically relevant) modelling of the additive cost component that varies over country partner and

product, it is the reduction of the transport costs “per se” that overwhelmingly explains the downward trend of overall transport costs observed over the period, rather than trade composition effects. ||||||| Updated upstream

To prove this point requires a careful modelling of transport costs. Following Samuelson (1954), standard models of international trade have usually modeled trade costs as an *ad-valorem* tax equivalent (ie, as a constant percentage of the producer price per unit traded, part of the “iceberg cost” hypothesis).¹ However, a recent strand of the literature points out to the existence of an additive component, that is, a cost per unit traded.² Based on US sectoral data, our own estimates also bring out the importance of additive costs in international transport costs. This is obtained by providing an empirical decomposition of the structure of transport costs over time, in which we explicitly distinguish between *ad-valorem* and additive parts. To do so, we exploit information contained in the US Imports flows over 1974-2013, from which we get a measure of international transport costs as the difference between the import and the export prices, on a year-product-partner country basis. This database is the same as Hummels (2007), extended over the more recent years through (2005-2013).

Two main new findings emerge. First, additive transport costs are quantitatively sizeable. On average over 1974-2013, the additive cost is estimated to 1.8% and 2.9% of the export price in air and vessel transport respectively. This is slightly lower than our estimates for the *ad-valorem* component (3.5% and 3.2% for air/vessel respectively on average over the period). Put it differently, additive costs represent between 40 % and 50% of the overall transport costs, depending on the year and the transport model. To the best of our knowledge, our paper is the first to provide such an extensive quantitative measure of both *ad-valorem* and additive costs in total transport costs.³ This represents a valuable insight for calibrating related international trade or business cycle models. We also provide an empirical assessment of what standard international trade models lose by skipping additive transport costs. Quantitatively, the omission of the additive term leads to overestimate the *ad-valorem* component by roughly a factor 2. Further, the goodness of fit is systematically better when the additive component is included in the regression, even when taking into account the additional degrees of freedom.

Second, and most importantly, we find that the main source of the downward trend in overall transport costs over 1974-2013 does come from the reduction of transport cost “per se”, rather than from trade composition effects.⁴ This stands in sharp contrast to the con-

¹Rigourously speaking, the “iceberg cost” includes both the *ad-valorem* dimension of trade cost and the fact that these costs are paid in terms of the good that is traded. As this last element is irrelevant in our case, we use the terms “iceberg” and “*ad-valorem*” interchangeably, as commonly done in the literature.

²As documented by Irarrazabal *et al.* (2015), pricing structure in shipping, additive tariffs, distribution costs... often exhibit (at least partly) an additive structure.

³As we discuss below, the closest paper to us in this respect is Irarrazabal *et al.* (2015). However, given their database and their empirical approach, Irarrazabal *et al.* (2015) can only identify the ratio of the additive to the *ad-valorem* cost ($\frac{t_{ik}}{\tau_{ik}}$ in our terminology), that they interpret by expressing it in terms of the median export price by country-product (\tilde{p}_{ik}). By contrast, our estimation strategy enables us to uncover both values of the *ad-valorem* and the additive costs τ_{ik} and t_{ik} separately, in terms of the country-product export price \tilde{p}_{ik} .

⁴Between 1974 and 2013, transport costs have decreased by roughly 50% in air shipping and 60% in

clusion obtained by Hummels (2007) on the same database (until 2004). Importantly, we show that the difference of results can be attributed to the modeling of the additive component: Allowing the additive costs to vary across products and country partners (rather than being constant as in Hummels (2007)), turns out to be key in the decomposition of underlying sources of the decrease of overall transport costs observed over the period.

In both aspects, our results thus point the importance of the additive component in accounting for international transport costs. In this respect, it contributes to the literature that challenges the dominant role of iceberg costs in international trade. As pointed out by Alchian and Allen (1964), the relative price of two varieties of some good will depend on the level of trade costs as long as they display an additive component. In this context, the relative demand for more expensive/higher quality product goods increases with trade costs (“shipping the good apples out”). This is consistent with the findings by Hummels and Skiba (2004), who estimate the elasticity of freight rates with respect to price to be well below unity. Also, their estimates imply that doubling freight costs increases average free alongside (fas) export prices by 80 to 141 percent, consistent with high quality goods being sold in markets with high freight costs. Lashkaripour (2017) challenges this view. Highlighting that more expensive goods are systematically heavier (and hence more costly to transport⁵), he finds an average transport cost elasticity much closer to 1 using firm-level data on Colombian imports. This result is also confirmed on more aggregate US, sector-level trade data. The debate is not over yet, as recent empirical studies based on micro-level data conversely provide a strong empirical support to the role of additive costs (i.e., cost per unit exported) in international trade costs. Based on a firm-product-level database of French exporters, Martin (2012) finds that firms charge higher unit values for exports to more remote countries, in contradiction with the ad-valorem hypothesis.⁶

Closely related to our paper is the work by Irarrazabal *et al.* (2015), which develop a structural framework for inferring additive trade costs from firm-level trade data. Based on Norwegian firm-level export data in 2004, they find that the ratio of additive to ad-valorem trade costs is about 14% of the export price. Our results share in common with Irarrazabal *et al.* (2015) the important role of the additive component of international trade costs. Yet, our paper complements their findings in two main respects. First, if our study covers a narrower set of trade costs focused on transport costs, our empirical

vessel shipping.

⁵Yet, one can be concerned by the generality of this result. While the positive correlation between weight and price seems reasonable for goods from the second industrial revolution like cars, it is dubious in the case of ITC goods whose importance in international trade has been rising since the end of the 20th century.

⁶Beyond the positive aspect, several recent papers also point out the normative implications of additive trade costs. Sorensen (2014) extends Melitz (2003)’s seminal model of international trade by including additive trade costs, in addition to the ad-valorem component. A key analytical result is that the welfare gain from a reduction in trade barriers is higher for a decrease in additive costs than a decrease in ad-valorem costs, due to the alteration of relative prices in a heterogeneous-firms trade framework. Calibrating on Norwegian firm-level data for 2004, Irarrazabal *et al.* (2015) find that an additive import tariff reduces welfare and trade by more than an identically-sized ad-valorem tariff. While these results suggest that important welfare gains can be achieved by reducing additive trade costs, not much progress has been done in quantifying such gains. One potential reason is the lack of an empirical characterization of the additive component of trade costs (the one exception being Irarrazabal *et al.* (2015)). One contribution of the paper is to fill this gap.

analysis allows us to provide distinct measures of the levels of both the iceberg and the additive trade costs. We thus obtain that, on average, the additive cost amounts to 1.8% and 2.9% of the export price in air and vessel transport respectively; the average estimated value for the ad-valorem component being of 3.5% and 3.2% for air/vessel respectively. From this, we can rebuilt the ratio in similar terms to them, thereby gaining in generality in this respect. Straightforward calculation yields a ratio of additive to multiplicative international transport costs around 2% (expressed in terms of the export price) in both Irarrazabal *et al.* (2015) and our paper.⁷ This makes us confident in our quantitative assessment of the sizes of international transport costs. Second, we exploit exhaustive information about the imports flows of the US over a large time span from 1974 to 2013. In this respect, our results deliver a broader view of the magnitude of additive costs in international trade over time. In particular, we show that the modeling of additive costs is of critical importance in determining the underlying sources of the trends patterns of international transport costs observed since 1974.⁸

=====

To prove this point requires a careful modelling of transport costs. Following Samuelson (1954), standard models of international trade have usually modeled trade costs as an *ad-valorem* tax equivalent (ie, as a constant percentage of the producer price per unit traded, part of the “iceberg cost” hypothesis).⁹ However, a recent strand of the literature points out to the existence of an additive component, that is, a cost per unit traded.¹⁰ Based on US sectoral data, our own estimates also bring out the importance of additive costs in international transport costs. This is obtained by providing an empirical decomposition of the structure of transport costs over time, in which we explicitly distinguish between ad-valorem and additive parts. To do so, we exploit information contained in the US Imports flows over 1974-2013, from which we get a measure of international transport costs as the difference between the import and the export prices, on a year-product-partner country basis. This database is the same as Hummels (2007), extended over the more recent years through (2005-2013).

<sup>16</sup>On top of the previously cited papers about additive costs, our paper also relates to Kropf and Sauré (2016), which estimate the size and shape of per-shipment costs bases on Swiss data, and to Alessandria *et al.* (2010), Hornok and Koren (2015b) or Hornok and Koren (2015a), which point out the role of per-shipment costs (among which, administrative costs) in generating some “lumpiness” in international trade transactions.

checks of our results. Section 7 concludes.

**VV: Trop de “thus” dans l’intro.**

**VV: Affirmer nettement la difference avec Hummels !! Pour Vincent, notre vrai resultat est la (il y a une baisse des couts de transport, les effets de compo nexpliquent pas tout), et cest cela que nous devrions vendre, davantage que lhistoire multiplicatif/additif, une question de geek en trade qui limitera forcment le type de revue auquel on pourra soumettre. EST-CE BON AINSI?**

## 2 Data Sources and Empirical Methodology

### 2.1 A measure of transportation costs

Our analysis of transportation costs consists in exploiting the difference between commodity-level export and import prices, as in Hummels (2007) (among others). The database we use to construct our measure of transport costs comes from US annual Imports of Merchandise provided by the Census bureau,<sup>17</sup> spanning from 1974 to 2013. We first use customs values, quantities and freight costs to recover free-alongside (fas) and cost-insurance-fret (cif) prices, by goods, country of origin and transportation mode.<sup>18</sup> More precisely, the (unit) fas price is computed as the total “customs value” in the US trade statistics divided by the shipping weight; in other words, it is the price for one kg of the good net of transportation costs. The cif price is then computed as the sum of the customs value and freight charges, once again divided by the shipping weight. Our dependant variable is finally computed as the ratio of the cif price divided by the fas price. Higher than 1, the variable provides a measure of transport costs as a proportion of the good’s price, an *ad-valorem* equivalent. This is a quite standard and widespread strategy, as emphasized by Anderson and Van Wincoop (2004). `##### Updated upstream`

`=====`

`#####` Stashed changes Obviously, this dataset is not immune of limitations. First, it restricts our analysis to the study of international transport costs, as our measure of the cif-fas price gap only covers freight, insurance and handling costs. It is thus silent about the others dimensions of international trade costs, unlike Irarrazabal *et al.* (2015). Further, in terms of transport costs *per se*, our measure based on the cif-fas price gap captures the quantitative costs due to insurance, handling and freight, but it omits the other dimension of transport costs related to the time value of goods in transit. In this respect, this dataset embraces only a partial view of international transport barriers. However, it is also

<sup>17</sup>More information available at: [http://www.census.gov/foreign-trade/reference/products/catalog/fl\\_imp.txt](http://www.census.gov/foreign-trade/reference/products/catalog/fl_imp.txt)

<sup>18</sup>The related literature commonly refers to the fob price rather than the fas price. The fas price (for “Free Alongside Ship”) means that the seller must transport the goods all the way to the dock, close enough to be reached by the crane of the ship it will be transported in. It is also the seller’s responsibility to clear the goods for export. The fob price (for “Free on Board”) means that the seller is obligated to bring the goods all the way to the port, clear the goods for export, and see that they are loaded onto the ship nominated by the buyer. Once the goods clear the railing of the vessel the buyer assumes the risk. Note that this term is used exclusively for maritime and inland waterway transport. While both terms are closely related, we refer to the fas price as the price considered by the US Foreign Trade Statistics.

clear that direct transport costs do represent a sizeable share of trade costs. According to Anderson and Van Wincoop (2004), the 21% markup over production costs coming from transport costs includes both directly measured freight costs (10.7%) and 9% tax equivalent of “indirect” costs related to the time value of goods on their way to their export market (including holding cost for the goods in transit, inventory cost due to buffering the variability of delivery dates, preparation costs associated with shipment size...). Still, the evidence summarized in Anderson and Van Wincoop (2004) points to a persisting importance of direct transport costs, especially compared to other trade barriers. They remain more important than, e.g., policy barriers (8% tax equivalent), language barrier (7%) or information cost (6%).<sup>19</sup> Furthermore, our data is based on a single and reliable customs source with a wide time and geographical coverage, and it allows the computation of a direct transport cost measure. This limits the measurement error bias. Therefore, we strongly believe that exploiting this database delivers useful and reliable insights on the structure of international trade costs. Last, as mentioned by Lafourcade and Thisse (2011), our transport costs measures is based on actual trade flows, i.e. ignoring those flows that did not happen because of presumably prohibitive transport costs. In light of this, the estimated values that we obtain can be viewed as the lower bounds of the “true” transport costs.

Yet, this dataset also has (at least) three advantages. First, it delivers a strong statistical reliability arising from a single, homogenous and trustworthy customs source. Based on customs declarations, the US Imports database inventories all imports (both values and quantities), by country of origin, to the United states at the HS 10-digit level, with a concordance code to the SITC 5-digit coding system. This will be crucial to compute transport costs, as we detail below. In addition, the database reports information regarding freight, insurance and handling expenditures by transportation mode, ocean (or “vessel”) and air. We will make use of this to enlighten potential differences in the dynamics of transport costs across transportation mode. Second, using this dataset allows us to have both the import price and the export price for the same good (for a given origin country). This is highly valuable, as it gives us a direct measure of international transport costs (at the country/sector level), from which we can estimate separately the *levels* of both the iceberg costs and of the additive costs. Third, this dataset is available over a long time span, which we exploit by providing an analysis of the trend patterns of international transport costs over the period 1974-2013.

We estimate international transport costs at the 3-digit classification level, even if data series on the cif and fas prices are available at the 5-digit classification level. As detailed below, the use of a nonlinear estimator triggers computational limitations that limit the level of possible detail, especially when covering a long period of time. Yet, we ensure the robustness of these results by conducting the estimations at the 4-digit level for some selected years.<sup>20</sup> Depending on the considered year, this leaves us with around 200 sectors,

---

<sup>19</sup>In his survey, Hummels (1999) mentions several papers which all point that transport costs pose a barrier similar in size, or larger than tariffs. In the same vein, Limao and Venables (2001) highlight the importance of infrastructures for trade costs in general, through their impact on transport costs.

<sup>20</sup>The selected years for the 4-digit level estimations are: 1974, 1977, 1981, 1985, 1989, 1993, 1997,

from approximately 200 countries of origin.

## 2.2 Empirical specification

**The estimated equation** Our purpose is to provide time-varying estimates of the size of ad-valorem and additive costs among total transport costs. To do so, we start from the equation that expresses the price  $p$  of a good paid by the importer (import, or cif price) as a function of the producer price  $\tilde{p}$  (export, or fas price), given both per-kg ( $t$ ) and ad-valorem ( $\tau$ ) transport costs, according to:

$$p = \tau \tilde{p} + t \quad (1)$$

As usual in the literature, the iceberg trade costs are denoted  $\tau$  (with  $\tau \geq 1$ ,  $\tau = 1$  meaning no ad-valorem trade costs), while additive trade costs are labeled  $t$  (with  $t \geq 0$ ,  $t = 0$  implying no additive costs). Let us denote  $i$  the origin country, and  $k$ , the product (at the 5-digit level). Transforming the above equation (1) as ratio in order to get the percentage change in prices induced by transportation, we thus get the following baseline specification at the root of our estimation (skipping the year and transport-mode dimensions in the notations for reading convenience):

$$\frac{p_{ik}}{\tilde{p}_{ik}} - 1 = \tau_{ik} - 1 + \frac{t_{ik}}{\tilde{p}_{ik}} \quad (2)$$

**Estimation Strategy** We follow Irarrazabal *et al.* (2015) by considering that *i*) both ad-valorem and additive costs are separable between the origin country ( $i$ ) and the product ( $k$ ) dimensions, and *ii*) this separability is in a multiplicative way for the former and an additive way for the latter. In other words,  $\tau_{ik}$  and  $t_{ik}$  from Equation (2) are written as:<sup>21</sup>

$$\tau_{ik} = \tau_i \times \tau_k \quad (3)$$

$$t_{ik} = t_i + t_k \quad (4)$$

As a result, our underlying structural equation is specified as:

$$\frac{p_{ik}}{\tilde{p}_{ik}} - 1 = \tau_i \times \tau_k - 1 + \frac{t_i + t_k}{\tilde{p}_{ik}}$$

The ratio  $\frac{p_{ik}}{\tilde{p}_{ik}}$  has a lower bound of one, since by construction, the cif price  $p$  cannot be lower than the fas price ( $p_{ik} > \tilde{p}_{ik}$ ). Taking into account this constraint in the estimate implies that the error term should be always positive and multiplicative. We ensure that this constraint is fulfilled by specifying the error term as follows:

---

2001, 2005, 2009, 2013. Comparing different levels of aggregation is useful to check differences and the presence of biases precisely due to aggregation. However, we obtain no substantial difference between the estimation results conducted at the 3 and 4-digit levels. Estimation results at the 4-digit classification level are reported in Appendix C.

<sup>21</sup>Notice that, given the magnitude or order of transport costs, assuming an additive or a multiplicative form does not make a substantial difference since, for small values (as we obtain), we have  $\tau_i \times \tau_k - 1 \simeq (\tau_i - 1) + (\tau_k - 1)$  and  $t_i + t_k \simeq (1 + t_i) \times (1 + t_k) - 1$ .

$$\frac{p_{ik}}{\tilde{p}_{ik}} - 1 = \left( \tau_i \times \tau_k - 1 + \frac{t_i + t_k}{\tilde{p}_{ik}} \right) \times \exp(\epsilon_{ik})$$

where  $\epsilon_{ik}$  follows an normal law centered on 0. Considered in logs, the above equation becomes:

$$\ln \left( \frac{p_{ik}}{\tilde{p}_{ik}} - 1 \right) = \ln \left( \tau_i \times \tau_k + \frac{t_i + t_k}{\tilde{p}_{ik}} - 1 \right) + \epsilon_{ik} \quad (5)$$

The non-linearity of Equation (5) implies that it cannot be estimated using standard linear estimators. All estimates are thus performed using non-linear least squares.<sup>22</sup> Yet, the use of a nonlinear estimator triggers computational limitations that limit the level of possible detail, especially when covering a long period of time. Confronted to this arbitrage, we estimate international transport costs at the 3-digit level as our benchmark classification, even though data series are available at the 5-digit classification level ( $k$ ). In other words, this amounts making the additional assumption, that all products  $k$  in a 3-digit sector  $s$  share the same structure of costs.<sup>23,24</sup>

This drives us to estimate a modified version of Equation (5), specified as:

$$\ln \left( \frac{p_{ik}}{\tilde{p}_{ik}} - 1 \right) = \ln \left( \tau_i \times \tau_{s(k)} + \frac{t_i + t_{s(k)}}{\tilde{p}_{ik}} - 1 \right) + \epsilon_{ik} \quad (6)$$

where  $\tau_i$ ,  $\tau_{s(k)}$ ,  $t_i$  and  $t_{s(k)}$  are the parameters to be estimated, i.e., fixed effects specific to each origin country  $i$  and sector  $s$  (at the 3-digit classification level), and  $\epsilon_{ik}$  the residual centered on 0.<sup>25</sup> To eliminate the potential influence of outliers, we excluded 5 percent of the upper and lower tails of the distribution in the regression variables. These cut-offs are aimed at eliminating reporting or coding errors. We estimate this equation for each year

<sup>22</sup>The basis of the method is to approximate the model by a linear one and to refine the parameters by successive iterations. The intuitive criterion for convergence is that the sum of squares of residuals does not increase from one iteration to the next. See Wooldridge (2001) for more details.

<sup>23</sup>We provide a decomposition variance exercise on the observed cif-fas price. As reported in Appendix B.3, the share of the observed variance that is accounted for by the between-sector ( $s$ ) variance is roughly similar to the between-product ( $k$ ) variance.

<sup>24</sup>One may object that we could preserve the estimation at the 5-digit level by running an OLS estimation on the equation taken in level, i.e. on the basis of Equation (2), specifying the error term additively. This would not solve the problem though, for three main complementary reasons. First, at the 5-digit level the number of fixed effects to include in the estimation would be very high, making the estimation computationally extremely burdensome, even in OLS. Imposing Equations (3) and (3) to reduce the number of fixed effects would drive us back to the non-linearity issue. Second, making the error term (specified as following a normal law centered on 0) enter Equation (2) additively implies negative values for some of the estimated residuals  $\hat{\epsilon}_{ik}$ , which is inconsistent with the constraint that  $\frac{p_{ik}}{\tilde{p}_{ik}} > 1$ . Third, estimating the equation in level does not eliminate the fact that it is non-linear by nature, as long as there are additive costs to estimate (see Equation (2) for  $t_{ik} \neq 0$ ).

<sup>25</sup>Note that, rigorously speaking, the precise equation that we estimate is the following:

$$\ln \left( \frac{p_{ik}}{\tilde{p}_{ik}} - 1 \right) = \ln \left( \sum_i \alpha_i^\tau \mathbb{1}_i \times \sum_{s(k)} \alpha_{s(k)}^\tau \mathbb{1}_{s(k)} + \frac{\sum_i \alpha_i^t \mathbb{1}_i + \sum_{s(k)} \alpha_{s(k)}^t \mathbb{1}_{s(k)}}{\tilde{p}_{ik}} - 1 \right) + \epsilon_{ik}$$

After proceeding to the estimation, we uncover the estimated values of the transport costs components  $\tau_i$ ,  $\tau_{s(k)}$ ,  $t_i$ ,  $t_{s(k)}$  from the obtained coefficients  $\alpha_z^x$  for  $x = \tau, t$  and  $z = i, s(k)$  (by year and transport mode). For reading convenience, we adopt a lighter expression of this equation by resorting to the notations of  $\tau_i$ ,  $\tau_{s(k)}$  and  $t_i$ ,  $t_{s(k)}$  as a short-cut.

over the period 1974-2013, for each of the transportation mode reported (air or vessel), on a sectoral-origin country basis ( $i, s$ ). Depending on the year considered, this leaves us with around 800 fixed effects to estimate by transport mode (at the 3-digit level).

**VV: Les explications accompagnant lequation estimee 6 ne sont pas claires : si  $\tau_i$ ,  $\tau_{s(k)}$ ,  $t_i$  et  $t_{s(k)}$  sont des effets fixes, alors  $\tau_i = t_i$  et  $\tau_{s(k)} = t_{s(k)}$  !!! Clarifier. Cf FOOTNOTE AJOUTEE? EST-CE OK AINSI?**

One key objective of the paper is to characterize the importance of additive costs relatively to ad-valorem costs. A natural way to answer this question is to perform estimations of Equation (6) constraining additive costs to be equal to zero, and compare the fitting properties and the explanatory power of the models. For each year and transport mode, we thus estimate two models: (a) when additive costs are excluded, in which case transport costs are modeled as iceberg costs only (Equation (7)), and (b) when transport costs are decomposed in the two additive and ad-valorem dimensions (Equation (6)). Under Model ((a)), the estimated equation simplifies as:<sup>26</sup>

$$\ln \left( \frac{p_{ik}}{\tilde{p}_{ik}} - 1 \right) = \ln (\tau_i \times \tau_{s(k)} - 1) + \epsilon_{ik}^{ice} \quad (7)$$

One may be concerned that the specification of Equations (6) or (7) might be subject to endogeneity bias, as the price set by the exporter may vary depending on the transport cost burden. Studies on the pricing-to-market behavior of firms (see Krugman, 1987) show that we cannot exclude that the export price set by the firm ( $\tilde{p}_{ik}$ ) is partly endogenous to the

---

<sup>26</sup>One may also object that a comprehensive study of the structure of transport costs should also include the third model with only additive costs. This has driven us to estimate this model as well, in which case the estimated equation is written according to:  $\ln \left( \frac{p_{ik}}{\tilde{p}_{ik}} - 1 \right) = \ln \left( \frac{t_i + t_{s(k)}}{\tilde{p}_{ik}} \right) + \epsilon_{ik}^{add}$ . The main result that emerges is that the model with additive costs only is dominated (in terms of quality of fit properties) by the model with multiplicative costs only (Equation (7)), which is itself dominated by the complete model (Equation (6)), anticipating on further results. These results are reported in the Online Appendix, available on the authors' webpages.

size of transport costs (for instance, the exporting firm absorbing (part of) the transport costs by reducing the *fas* price). However, we consider as a reasonable assumption that the exporting firm cannot influence the international transport cost sector, that would imply a causal effect of the firm’s prices on the transport costs value, except in the choice between air and vessel transport (that is beyond our scope of analysis). Otherwise stated, conditional to an export price and a transport mode, the gap between the export price declared to the custom data and the import price recorded by the US administration is beyond the firm’s control. In this respect, we are confident that our estimation strategy is immune from endogeneity problems.

After estimating Equation (6), we can re-built a measure of each component,  $\hat{\tau}_{is}^{adv} = \hat{\tau}_i \times \hat{\tau}_{s(k)}$  for the ad-valorem cost and  $\hat{t}_{is} = \hat{t}_i + \hat{t}_{s(k)}$  for the additive cost, that are country-sector specific, by year and transport mode. When assuming iceberg costs only (Equation (7)), we proceed similarly to get  $\hat{\tau}_{is}^{ice} = \hat{\tau}_i \times \hat{\tau}_s$ .<sup>27</sup> Similarly as Irarrazabal *et al.* (2015), we take the average over the sector-country dimension, using the values of each trade flow (*is*-specific) over total yearly trade as a weighting scheme. We thus recover a “synthetic estimate” of each type of transport cost: *a)*  $\hat{\tau}^{ice}$ , *b)*  $\hat{\tau}^{adv}$  and  $\hat{t}$ , for each year and transportation mode. These results are reported in Section 3.

### 3 Decomposing Transport Costs: The importance of the additive component

Our ambition to re-assess the underlying sources of the trend patterns of international transport costs requires a careful modeling of both the additive and the multiplicative components. The first step of analysis then consists in providing a quantification of the magnitude of transport costs over time (by transport mode), distinguishing whether the additive component  $t_{ik}$  is excluded or included in the estimated equation (Equation (6) or (7)). This allows us to provide estimates for the size of both the ad-valorem and the additive components of transport costs, and assess whether additive costs represent a sizeable component of transport costs. In this respect, these results *per se* also constitute our first original contribution to the literature. In Appendix B.2, we provide diagnostic tests about the goodness-of-fit measures, that confirm the empirical relevance of adding the additive component in the estimation.

#### 3.1 Decomposing transport costs over 1974-2013

Table 1 reports a summary of our results. It displays the mean and median values of each type of transport costs (either ad-valorem estimated alone or estimated along with additive costs), as well as the associated standard deviation, averaged over the period 1974-2013, for estimation driven both at the 3- and 4-digit sectorial level for different specifications and data. The first panel reports the results for a specification based on ad-

---

<sup>27</sup>In this case, notice that the equation could be estimated relying on a linear form. To preserve comparability of the results, we keep the same non-linear estimation method in both cases though.

valorem costs estimated alone (Equation (7)), while the second panel presents estimates for a specification involving both ad-valorem and multiplicative components (Equation (6)). Finally, the third panel reports the same set of descriptive statistics, but for the actual cif/fas ratio in our data.<sup>28,29</sup>

Table 1: Transport costs estimates: Summary

| Mean value over 1974-2013                                                                     |          |          |              |        |

Notes: Statistics are obtained weighting each observation by its value relative to total trade flows. The additive term is expressed in fraction of fas price. (\*): Four 4-digit estimation: 0n selected years. (\*\*): 1989 omitted in 3-digit estimation for air.

VV: Nos resultats sont en ad-valorem (multiplicatif du prix), ce qui explique qu'on a des pourcentages superieurs pour Vessel par rapport a Air. Spontanement, on sattend au contraire (les couts de fret sont plus importants dans laerien), mais en fait ces chiffres refletent simplement que les prix sont plus eleves dans laerien. En un mot, ces chiffres ne signifient pas que les couts montaires dans laerien sont infrieurs au vessel. Ceci devrait etre precise.

Reponse de Lise: Une facon de repondre a ca est de montrer le prix fob moyen dans l'aerien / vessel. Pour montrer que c'est plus eleve dans l'aerien. Fournir une estimation en \$ du cout par unit (kg) additif pourrait etre inter-

<sup>28</sup>In Appendix B, we report similar results for a sample of years, for both transport mode, at the 3 and 4-digit classification level. Results for all years (available at the 3-digit level) are reported in the Online Appendix, available on the authors' webpages.

<sup>29</sup>We present the estimation results for Air at the 3-digit level removing the year 1989, as the results reveal the presence of strong outliers that bias the estimates of transport costs upwards this particular year. Overall results (over the whole period) are not substantially affected if this year is included though. This can be uncovered from the results detailed year by year in the Online Appendix, available on the authors' webpages.

**essant aussi, apres tout c'est fondamentalement ca qu'ils sont.**

Table 1 calls for two types of comments. The first type is of statistical order. As displayed in Table 1, mean values are systematically higher than medians, by around one percentage point. This result is not surprising recalling that our key variable is by nature bounded to 0; therefore, outliers can only be positive, pushing the mean up compared to the median. One can also note that estimated total costs are systematically higher than observed costs, by 0.5 to 1 percentage point. This is first due to the fact that observed data are *de facto* trade-weighted (i.e., by the weight of each good in total trade) while our estimates are based on simple arithmetic means within sector and country. Furthermore, Table 1 reports values expressed in percentages (for the observed values,  $\frac{p_{ik}}{\bar{p}_{ik}} - 1$ , in %), whereas all our estimates are based on log-linearization. Therefore, what matters on the statistical ground is that the mean of our predicted values (based on logarithms) must be equal to the mean of the log-linearized data ( $\ln\left(\frac{p_{ik}}{\bar{p}_{ik}} - 1\right)$ ), which does not necessarily imply equality between values. Descriptive statistics showing that both observed and predicted values do match in logarithms are available upon request to the authors.

Coming now to interpretation, two main results emerge from Table 1. First, it provides estimation results about the size of the overall transport costs. From Table 1, we obtain an overall value of approximatively a 6% markup in ocean shipping, 5% markup in air shipping in average over 1974-2013.<sup>30</sup> If this seems modest in comparison with the 11% of markup obtained by Anderson and Van Wincoop (2004) over a set of industrialized countries, this stands in line with the results obtained by Hummels (2007) for the US economy.<sup>31</sup>

Second, and most importantly, Table 1 provides new quantitative evidence about the size of the additive component of transportation costs. Our methodology indeed allows us to go deeper into the structure of transport costs, that can be decomposed into an additive and an ad-valorem components. We thus find that the per-kg cost dimension is quantitatively sizeable. On average over the whole period, additive costs are estimated to 2.9% of the export price for ocean shipping, and 1.8%. This is slightly lower than the estimates for the ad-valorem component, which is estimated to 3.2% and 1.8% for vessel and air shipping respectively (on average over the period). Put it differently, the additive component amounts to 48.2% of total transport costs in Vessel, and 42.3% in Air. For both transport modes, the omission of the additive term seriously biases the ad-valorem term upward. In quantitative terms, the omission of the additive term leads to overestimate the

<sup>30</sup>Expressed as a markup over production costs, transport costs are equal to  $\frac{p-\bar{p}}{\bar{p}}$ . Under Model (A) (ad-valorem costs only), making use of the figures reported in Table 1 gives a markup of 5.8% in vessel, and 5.1% in air shipping (considering the mean value over the period). Under Model (B), total transport costs are equal to  $\frac{p-\bar{p}}{\bar{p}} = (\tau - 1) + \frac{t}{\bar{p}}$ . With  $\tau - 1 = 0.032$  and  $\frac{t}{\bar{p}} = 0.029$  in Vessel (as reported in Table 1), we get a value equal to 6.1% in Vessel. A similar calculus gives 4.3% in air transport.

<sup>31</sup>The difference of results with Anderson and Van Wincoop (2004) can be accounted for by a number of reasons. Anderson and Van Wincoop (2004) obtain this 11% markup as a rough value by aggregating various sources over a bunch of industrialized countries, with data mostly based on the second half of the 1990s. By contrast, our estimation of a 6% markup relies on a single source of data based on the US imports flows over 1974-2013. Beyond country coverage and the time sample, another plausible candidate explanation lays in the difference of empirical methodology: Anderson and Van Wincoop (2004)'s estimates are based on standard gravity equations, while ours come from a non-linear estimation of a "structural" decomposition of the difference between export and import prices.

ad-valorem component by roughly a factor 2. Further, these results provide quantitative estimates for the values of both additive and ad-valorem transport costs, which can be very useful for the related more theoretical papers, which need to calibrate their models.

Our estimation results about the size of additive transport costs can be compared to Irarrazabal *et al.* (2015), which constitute the most recent evidence on this question. Based on Norwegian trade data for 2004, Irarrazabal *et al.* (2015) estimate that the ratio of additive to ad-valorem trade costs amounts to 14% of the export price, ie  $\frac{t/\tau}{p} = 14\%$  expressed in our terminology. One important difference with respect to their work is that we can provide separate estimates for each cost component (additive and ad-valorem). From this, we can rebuilt the ratio in similar terms to them – allowing us to gain in generality in this respect. Making use of our estimates for 2004, we thus obtain a ratio  $\frac{t}{\tau p} = 2.8\%$  in ocean shipping, 1.8% in air transport. This may sound surprisingly low, in contrast to the 14% obtained by Irarrazabal *et al.* (2015). This can be accounted for by recalling the difference in the type of dataset - hence, of costs, embraced in each case. While the database of Irarrazabal *et al.* (2015) allows to study trade costs in general, our database covers a subset made of the monetary international transport costs (as we start from the gap between the import and the export prices). From Anderson and Van Wincoop (2004), we can infer that monetary transport costs approximatively represent 15% of total trade costs.<sup>32</sup> Plugging this into Irarrazabal *et al.* (2015) results, allows to deduce a ratio  $t/\tau$  of international transport costs to the export price  $\tilde{p}$  equal to 2.1% ( $0.15 \times 0.14$ ). This stands in line with our own results, and makes us confident in our quantitative assessment of the size of the additive component in international transport costs.<sup>33</sup>

## 4 Transport Costs time trends: The role of the additive component

In this section, we investigate the trend patterns of international transport costs over time, by exploiting the time dimension of our database. This focus is shared with part of the international trade literature, such as Hummels (2007) and Behar and Venables (2011). Many argue that transport costs have substantially decreased with technological advance

<sup>32</sup>Anderson and Van Wincoop (2004) estimate that monetary transport costs represent a 11% markup over production costs, and that total international trade costs represent 74%, so transport costs amount to  $11/74 = 15\%$  of total trade costs.

<sup>33</sup>See also Appendix B.2, which confirms the importance of the additive cost component through another perspective angle based on quality-of-fit diagnostic tests.

in transportation, infrastructure development and new communication technologies (see Lafourcade and Thisse, 2011). Glaeser and Kohlhase (2004) find that, over the twentieth century, the cost of moving goods have declined by over 90% in real terms. However, Hummels (2007) points out that trade composition effects dominate the characterization of time trends of international transport costs and that transport costs “per se” (i.e., *ceteris paribus* for given goods and origins) have not declined much. In this paper, we investigate the robustness of this result.

### 5 Transport Costs time trends: The role of the additive component

In this section, we investigate the trend patterns of international transport costs over time, by exploiting the time dimension of our database. This focus is shared with part of the international trade literature, such as Hummels (2007) and Behar and Venables (2011). Many argue that transport costs have substantially decreased with technological advance in transportation, infrastructure development and new communication technologies (see Lafourcade and Thisse, 2011). Glaeser and Kohlhase (2004) find that, over the twentieth century, the cost of moving goods have declined by over 90% in real terms. However, Hummels (2007) points out that trade composition effects dominate the characterization of time trends of international transport costs and that transport costs “per se” (i.e., *ceteris paribus* for given goods and origins) have not declined much. In this paper, we investigate the robustness of this result.

#### 5.1 A first look at the trend patterns

~~~~~ Stashed changes As a first step, Figure 1 displays the respective shares of additive (black area) and iceberg (grey area) components in total transport costs in total costs (the total of the two, expressed in percentage of the f.o.b. price), by transport mode for each year between 1974 and 2013.

Two main comments can be made. First, in both transport modes, the additive component appears of sizeable importance all over the period, as the share of additive costs remains roughly constant over time. Confirming the results obtained in Section 3, this suggests that additive costs are neither negligible in magnitude nor an erratic phenomenon.

Figure 1: Decomposing Transport costs (Yearly mean value, 3 digits, in % of the fas price)

By contrast, they represent an sizeable and structural dimension of international transport costs. Updated upstream

Second, considering the trend in total transport costs (the upper line in Figure 1), both air and vessel shipping exhibit a downward trend in overall transport costs since 1974, by -2.1% per year for mean air transport costs and -2.0% per year for mean ocean transport costs, implying a 50% decrease in Air and a 60% decrease in Vessel over the period.³⁴ On US data, Hummels (1999) obtains that overall transport cost declined from 6 % to 4 % of the import value between 1974 and 1996. For the same years, we obtain a total decrease from 6.9 to 4.2% in terms of the export price, on average for air shipping, and from 9.8% to 4.8% for ocean shipping. Overall, our results display trends that are close to those reported by Hummels (1999), with a magnitude of transport costs that appears higher in ocean shipping than for air transport over the period.

Second, considering the trend in total transport costs (the upper line in Figure 1), both air and vessel shipping exhibit a downward trend in overall transport costs since 1974, by -2.1% per year for mean air transport costs and -2.0% per year for mean ocean transport costs, implying a 50% decrease in Air and a 60% decrease in Vessel over the period.³⁵ On

³⁴One may be puzzled for by the high magnitude of estimates for the beginning of the period (until 1980 approximately) for ocean transport. Hummels (2007) finds similar outcomes on tramp prices indexes, and suggests the oil shock as a likely culprit, in a context where technological progress was quicker in aviation than in vessel, allowing a better dampening of oil shocks on air freight rates. In a related manner, one may worry that the strong decrease in transport costs documented in Figure 1 springs from high oil-shock related transport costs in 1974. However, computing the time trends from 1980 does not dramatically change the picture. The yearly trend from 1980 is -2% for mean air transport costs and -1.6% for mean vessel transport costs. We thus choose to exploit the whole time dimension of our database by taking 1974 as starting date of our time trend analysis.

³⁵One may be puzzled for by the high magnitude of estimates for the beginning of the period (until 1980 approximately) for ocean transport. Overall, our results display trends that are close to those reported by Hummels (1999), with a magnitude of transport costs that appears higher in ocean shipping than for air transport over the period.

Before making any definite statement about this though, it is worth emphasizing that the time trend of international transport costs depends on both *i)* the evolution of per product and per partner “*ceteris paribus*” transport costs and *ii)* the evolution of the composition of trade. Total transport costs may thus have decreased over time because the share of neighbor countries in total US trade or the share of goods cheaper to transport has increased (explanation *ii)*), independently of any change in transport costs *per se*. As emphasized by Hummels (1999) or Hummels (2007), it is hence necessary to eliminate the composition effects of trade flows to isolate the evolution of “*ceteris paribus*” international transport costs, i.e. per product- and per partner- transport costs.

iiiiiii Updated upstream

A word on Hummels’ methodology At this point, let us make a brief summary of Hummels’ methodology. He starts from the following specification of the ratio of destination to origin prices modelled as $p_{ikt} = \tilde{p}_{ikt} + \frac{f_{ikt}}{\tilde{p}_{ikt}}$, with f the shipping charge per kg shipped. Further, and as in Hummels and Skiba (2004), Hummels (2007) writes the per kg shipping charge as $f_{ikt} = \tilde{p}_{ikt}^{1-\beta} X_{ikt}$, where X_{ikt} represents other costs shifters (distance, port quality, etc.) Accordingly, the transport cost measure writes down as:

$$TC_{ikt} \equiv \frac{p_{ikt} - \tilde{p}_{ikt}}{\tilde{p}_{ikt}} = \tilde{p}_{ikt}^{\beta} X_{ikt} \quad (8)$$

Notice that β can be interpreted as the elasticity of transport costs to the export price (in absolute value). As such, a value of $\beta = 0$ corresponds to the standard case of “iceberg” costs, in which transport costs are purely ad valorem. At the other extreme, $\beta = 1$ means that all transport costs are additive. Accordingly, the estimated value of β can be interpreted as the share of additive costs in total transport costs. Equation (9) is the baseline specification from which Hummels (2007) decomposes the changes in transport costs over time between trade composition effects and changes in “pure” transport costs, as described with more details in Appendix D.2.

In doing so, Hummels (2007) implicitly assumes β constant across the triplet origin country origin/product/year. In light of the economic interpretation of β , this means that the share of additive costs in total costs does not vary across these dimensions. However, our results of Section 3 (on a year-to-year basis, see Appendix B) and of Figure 1, yield to cast some doubt on the empirical relevance of this assumption. As reported in Figure 1, if overall transport costs have decreased over time, it is also the case for each additive

change the picture. The yearly trend from 1980 is -2% for mean air transport costs and -1.6% for mean vessel transport costs. We thus choose to exploit the whole time dimension of our database by taking 1974 as starting date of our time trend analysis.

and multiplicative components. In particular, the share of additive costs appears to be varying over time, in both transport modes. On top of this, one may wonder about the constancy of the share of additive costs along the couple (product/origin country). We investigate this point deeper by reporting the histogram of the distribution of the share of additive costs

stop here ===== Before making any definite statement about this though, it is worth emphasizing that the time trend of international transport costs depends on both *i*) the evolution of per product and per partner “ceteris paribus” transport costs and *ii*) the evolution of the composition of trade. Total transport costs may thus have decreased over time because the share of neighbor countries in total US trade or the share of goods cheaper to transport has increased (explanation *ii*)), independently of any change in transport costs *per se*. As emphasized by Hummels (1999) or Hummels (2007), it is hence necessary to eliminate the composition effects of trade flows to isolate the evolution of “ceteris paribus” international transport costs, i.e. per product- and per partner- transport costs.

A word on Hummels’ methodology At this point, let us make a brief summary of Hummels’ methodology. He starts from the following specification of the ratio of destination to origin prices modelled as $p_{ikt} = \tilde{p}_{ikt} + \frac{f_{ikt}}{\tilde{p}_{ikt}}$, with f the shipping charge per kg shipped. Further, and as in Hummels and Skiba (2004), Hummels (2007) writes the per kg shipping charge as $f_{ikt} = \tilde{p}_{ikt}^{1-\beta} X_{ikt}$, where X_{ikt} represents other costs shifters (distance, port quality, etc.) Accordingly, the transport cost measure writes down as:

$$TC_{ikt} \equiv \frac{p_{ikt} - \tilde{p}_{ikt}}{\tilde{p}_{ikt}} = \tilde{p}_{ikt}^{-\beta} X_{ikt} \quad (9)$$

Notice that β can be interpreted as the elasticity of transport costs to the export price (in absolute value). As such, a value of $\beta = 0$ corresponds to the standard case of “iceberg” costs, in which transport costs are purely ad valorem. At the other extreme, $\beta = 1$ means that all transport costs are additive. Accordingly, the estimated value of β can be interpreted as the share of additive costs in total transport costs. Equation (9) is the baseline specification from which Hummels (2007) decomposes the changes in transport costs over time between trade composition effects and changes in “pure” transport costs, as described with more details in Appendix D.2.

In doing so, Hummels (2007) implicitly assumes β constant across the triplet origin country origin/product/year. In light of the economic interpretation of β , this means that the share of additive costs in total costs does not vary across these dimensions. However, our results of Section 3 (on a year-to-year basis, see Appendix B) and of Figure 1, yield to cast some doubt on the empirical relevance of this assumption. As reported in Figure 1, if overall transport costs have decreased over time, it is also the case for each additive and multiplicative components. In particular, the share of additive costs appears to be varying over time, in both transport modes. On top of this, one may wonder about the constancy of the share of additive costs along the couple (product/origin country). We investigate this point deeper by reporting the histogram of the distribution of the share of additive costs in total costs. To do so, we start from Equation (2) with the trade costs measure on

the left-hand side, making use of our estimates for both the additive and multiplicative components. From this, we can obtain that the elasticity of transport costs to the export price, ie β , is equal to

$$\beta_{ikt} \equiv \frac{\partial TC_{ikt}}{\partial \tilde{p}_{ikt}} \frac{\tilde{p}_{ikt}}{TC_{ikt}} = \frac{\hat{t}_{ikt}/\tilde{p}_{ikt}}{\hat{t}_{ikt}/\tilde{p}_{ikt} + \hat{\tau}_{ikt}}$$

~~~~~ Stashed changes

## 5.2 Empirical specification

~~~~~ Updated upstream The above results point out that the share of additive costs in total transport costs is not constant across the triplet year/product/origin country, thereby contrasting the implicit Hummel’s (2007) assumption. One may speculate that it is not innocuous regarding the analysis of the underlying determinants of transport costs trend patterns. This drives us to provide a decomposition of the transport costs trends (between the trade composition effects and the “pure” transport costs time trends), that explicitly takes into account the varying share of additive costs over time, country partner and product.<sup>36</sup>

Estimation strategy Estimation driven in Section 3 provides us with the additive and ad-valorem measures of international transport costs (Equation (6)), that vary over time, product and origin country. Starting from these values, we extract the “ceteris paribus” transport cost measure, for each additive and multiplicative cost component (by transport mode) by the mean of a time fixed effect (see details below). For each cost component (additive and ad-valorem), comparing the unfitted measure and the fitted measure (composition effects excluded) allows to characterize if the decrease observed over the period is due to trade composition effects (for instance, changes in the country partners, in the type/ quality of products traded), or if it is the “ceteris paribus” costs (for instance, insurance or handling costs) that have reduced over time. We conduct the same analysis on a overall transport costs measure, built by agglomerating the two estimated components (additive and iceberg) in a unified measure of transport costs.³⁷

The remaining question is then, how to eliminate the composition effects? Our reasoning obeys the following rationale. Starting from the values of each additive and ad-valorem transport cost measure estimated in Section 3, we extract the changes over time in the “ceteris paribus” transport cost dimension by assuming a composition of trade flows by country partner and product that is constant throughout the period, and equal to the one observed in 1974. One advantage of this method is to yield measures of transport costs (fitted and unfitted) that are easily comparable between transport modes and transport cost components.

³⁶See Appendix D.2 for a detailed comparison of Hummel’s (2007) methodology and ours.

³⁷Note that the “unfitted” total transport costs are virtually the same as those reported in Figure 1, but reported from another perspective (basis 100 in year 1974).

Estimation strategy This empirical strategy can be described as a two-stage process. First, for each transport costs component (additive/multiplicative), we decompose the estimated measure in the three product/country/time dimensions, using fixed effects.

=====

5.3 Empirical specification

The above results point out that the share of additive costs in total transport costs is not constant across the triplet year/product/origin country, thereby contrasting the implicit Hummel’s (2007) assumption. One may speculate that it is not innocuous regarding the analysis of the underlying determinants of transport costs trend patterns. This drives us to provide a decomposition of the transport costs trends (between the trade composition effects and the “pure” transport costs time trends), that explicitly takes into account the varying share of additive costs over time, country partner and product.³⁸

Estimation strategy Estimation driven in Section 3 provides us with the additive and ad-valorem measures of international transport costs (Equation (6)), that vary over time, product and origin country. Starting from these values, we extract the “ceteris paribus” transport cost measure, for each additive and multiplicative cost component (by transport mode) by the mean of a time fixed effect (see details below). For each cost component (additive and ad-valorem), comparing the unfitted measure and the fitted measure (composition effects excluded) allows to characterize if the decrease observed over the period is due to trade composition effects (for instance, changes in the country partners, in the type/ quality of products traded), or if it is the “ceteris paribus” costs (for instance, insurance or handling costs) that have reduced over time. We conduct the same analysis on a overall transport costs measure, built by agglomerating the two estimated components (additive and iceberg) in a unified measure of transport costs.³⁹

The remaining question is then, how to eliminate the composition effects? Our reasoning obeys the following rationale. Starting from the values of each additive and ad-valorem transport cost measure estimated in Section 3, we extract the changes over time in the “ceteris paribus” transport cost dimension by assuming a composition of trade flows by country partner and product that is constant throughout the period, and equal to the one observed in 1974. One advantage of this method is to yield measures of transport costs (fitted and unfitted) that are easily comparable between transport modes and transport cost components.

Estimation strategy This empirical strategy can be described as a two-stage process. First, for each transport costs component (additive/multiplicative), we decompose the estimated measure in the three product/country/time dimensions, using fixed effects. ~~~~~~
Stashed changes

³⁸See Appendix D.2 for a detailed comparison of Hummel’s (2007) methodology and ours.

³⁹Note that the “unfitted” total transport costs are virtually the same as those reported in Figure 1, but reported from another perspective (basis 100 in year 1974).

For the estimated ad-valorem component, we thus estimate the following equation:

$$\ln(\widehat{\tau}_{ikt}) = \delta + \underbrace{\sum_{i \neq \text{ARG}} \alpha_i \cdot \mathbb{1}_i}_{(a)} + \underbrace{\sum_{s(k) \neq 011} \beta_{s(k)} \cdot \mathbb{1}_{s(k)}}_{(b)} + \underbrace{\sum_{t \neq 1974} \gamma_t \cdot \mathbb{1}_t + \epsilon_{ikt}}_{(c)} \quad (10)$$

Updated upstream where $\mathbb{1}_i$ and $\mathbb{1}_{s(k)}$ represent country- and sector- fixed effects.⁴⁰ Equation (10) is estimated using OLS, with a weighting scheme based on the value of each flow in the total value of flows the considered year. As for the additive component, given that the sector fixed effect and the country fixed effect are additive rather than multiplicative by construction, we estimate the following equation using non-linear least squares (using the same weighting scheme):⁴¹ ===== where $\mathbb{1}_i$ and $\mathbb{1}_{s(k)}$ represent country- and sector- fixed effects.⁴² Equation (10) is estimated using OLS, with a weighting scheme based on the value of each flow in the total value of flows the considered year. As for the additive component, given that the sector fixed effect and the country fixed effect are additive rather than multiplicative by construction, we estimate the following equation using non-linear least squares (using the same weighting scheme):⁴³ Stashed changes

$$\ln(\widehat{\tau}_{ikt}) = \ln \left(\delta + \underbrace{\sum_{i \neq \text{ARG}} \alpha_i \cdot \mathbb{1}_i}_{(a)} + \underbrace{\sum_{s(k)} \beta_{s(k)} \cdot \mathbb{1}_{s(k)}}_{(b)} \right) + \underbrace{\sum_{t \neq 1974} \gamma_t \cdot \mathbb{1}_t + \epsilon_{ikt}}_{(c)} \quad (11)$$

As displayed in Equations (10) and (11), the objective is to decompose the estimated transport cost component in three components: The country dimension (Term (a)), the product dimension (Term (b)) and the “ceteris paribus” transport costs time trend (Term (c)). Notice that Equations (10) and (11) preserve our specification of the ad-valorem and additive costs of Equations (3) and (4), as we consider that the iceberg cost is the product of the country of origin and the good dimension, while the additive cost is the sum of the two dimensions. Both equations are estimated by transport mode.

In this exercise, we are interested in isolating the change in the time dimension of the each transport cost component. This constitutes the second stage of our procedure. As for the ad-valorem component defined in $[1; +\infty]$, from the estimation of Equation (10),

⁴⁰Throughout the exercise, we consider Argentina, the sector 011 and the first year of our dataset 1974, as references for the country-, product- and year- dummies.

⁴¹For sake of notational simplicity, we do not distinguish the coefficients associated to the fixed effects between Equations (10) and (11), even if they are specific to the type of transport costs considered (e.g., the series of γ_t differs from one estimation to the other). Note that we impose the same weighting scheme as for the OLS regression (based on the relative value of the flow).

⁴²Throughout the exercise, we consider Argentina, the sector 011 and the first year of our dataset 1974, as references for the country-, product- and year- dummies.

⁴³For sake of notational simplicity, we do not distinguish the coefficients associated to the fixed effects between Equations (10) and (11), even if they are specific to the type of transport costs considered (e.g., the series of γ_t differs from one estimation to the other). Note that we impose the same weighting scheme as for the OLS regression (based on the relative value of the flow).

we built the variable Γ_t^{adv} , for each year $t \geq 1974$, according to:⁴⁴

$$\Gamma_t^{adv} = 100 \cdot \frac{\bar{\tau}_{1974} \cdot \exp(\gamma_t) - 1}{\bar{\tau}_{1974} - 1} \quad (12)$$

with $\bar{\tau}_{1974} = \exp(\delta + \sum_i \alpha_i + \sum_s \beta_s)$ the mean ad-valorem transport cost in 1974. In plain words, we measure how these costs have changed over time by blocking the composition of trade flows by product and country partners to the one observed in 1974 (the beginning of our sample).

As for the additive cost defined in $[0; +\infty]$, we built the variable Γ_t^{add} , the reference year being 1974 (ie, with $\gamma_{1974} = 0$) according to:

$$\Gamma_t^{add} = 100 \cdot \exp(\gamma_t) \quad (13)$$

As a result, the two series (for Γ_t^{adv} and Γ_t^{add}) have a straightforward interpretation in percentage changes from the initial value of 100 for $t = 1974$.

Last, we rebuild a measure of total transport costs as the sum of the two components (additive and iceberg), on both the unfitted measures and the “ceteris paribus” estimated transport costs (composition effects excluded). Details are reported in Appendix D.

5.4 Characterizing the time trends in transport costs

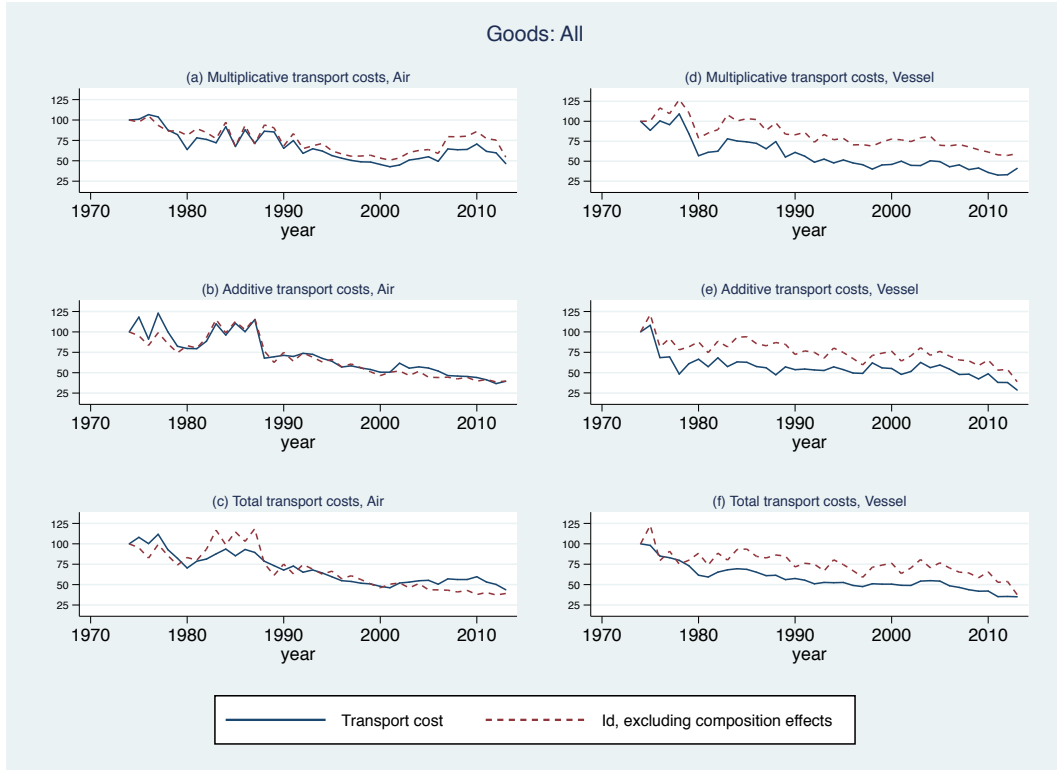

Figure 2 reports the results.⁴⁵ Panels (a), (b) and (c), we report the time changes of the ad-valorem costs, the additive costs and the total costs respectively, for Air transport (starting from the reference value 100 in 1974). Panels (d), (e) and (f) report the results for Vessel. In each panel, we report the evolution of transport costs for both the unfitted (plain blue line) and the fitted (dotted red line) measures.

Three main results emerge from Figure 2. First, in accordance with Figure 1, we find that international transport costs have substantially decreased over the period, and in both transport modes. International transport costs were reduced by 50% between 1974 and 2013 in air shipping, and by 60% in maritime shipping. This stands in line with the related literature (see Hummels, 1999, Lafourcade and Thisse, 2011). Second, and as discussed in Section 3, the magnitude of the decrease is roughly of same order both the ad-valorem and the additive components. Third, and most importantly, we find that composition effects do not play a major role in accounting for the time trend of overall transport costs. Inspecting the panels of Figure 2, we do not find much evidence of a substantial difference between the unfitted transport costs measure and the “ceteris paribus” transport costs. This is particularly true in Air transport, for both the additive and ad-valorem components (Figure 2, panels (a) to (c)). Air transport costs were reduced by 50% between 1974 and 2013, and this is mainly attributable to a reduction in the “ceteris paribus” transport costs. Composition effects are more pronounced in vessel transport. Considering the raw series, maritime transport costs have decreased by 60% over the period, which can be

⁴⁴See details in Appendix D.

⁴⁵Figure 2 reports the results, all types of goods included. In Appendix D, we report the results at a more disaggregated level, distinguishing between primary and manufacturing goods.

Figure 2: Transport costs (with and without composition effects)

decomposed in a 50% decrease in transport costs *per se*, and a 10% reduction that comes from composition effects, in particular for the multiplicative component (panel (d)).

VV: Figure 2 : 1) peu lisible en ltat. Soit on conserve ces graphes, et dans ce cas-la, on commente la dynamique, pas seulement le debut et la fin; si on veut rester sur seulement le debut et la fin, mettre un tableau. 2) Pour Air : lorsqu'on exclut les effets de compo, les couts multi sont plus importants, les couts additifs ne bougent pas... et les couts totaux sont en-dessous ! Dconcertant. Peut-etre est-ce du la faon dont les couts sont repartis par secteur. 3) Pour Vessel, il y a de vrais effets de composition (sauf la dernire annee), il nest pas possible daffirmer quil ny en a pas.

5.5 Time trends in transport costs and the modeling of the additive component

This last result stands in sharp contrast with Hummels (2007), which obtains that the “*ceteris paribus*” transport costs had decreased more than the unfitted ones (over 1974-2004), suggesting an important role to composition effects. If anything, we find the opposite result here. This drives us to investigate this difference of result further. As we explain in more details in Appendix D, our empirical strategy differs from Hummels (2007) in one main dimension. Our characterization of the time trends in transport costs starts from our estimates of both the additive and the ad-valorem components (obtained in Section 3), as well as for the overall transport cost (rather than the actual cif-fas price gap). As di-

rect consequence, our methodology lets the ratio between the additive and the ad-valorem components of transport costs vary over the three time-product-partner country dimensions. This turns out to be of primary importance in the disentangling in the time trend of transport costs, between what comes from the trade composition effects and what comes from changes in the “ceteris paribus” transport cost dimension, as we show below.⁴⁶ To establish this point clearly, we replicate the method adopted by Hummels (2007) exposed above on our database (which is the same as his until 2004). The results are reported in Figure 3. The dotted line labeled “expenditure/import value” represents the unfitted measure of transport costs (TC_t in the above terminology) and the plain line labeled “fitted ad-valorem rate” is the measure of transport costs composition effects excluded (\widehat{TC}_t).

Figure 3: Characterizing the time trends: Applying Hummel’s (2007) method

These results stand in sharp contrast with the ones obtained with our methodology and reported in Figure 2. Applying Hummels’ (2007) method, we obtain that the composition effects tend to partially offset the decrease in transport costs in both air and vessel shipping (as the downward trend is of higher magnitude for the fitted than the unfitted rate, especially for Vessel).⁴⁷ This result is overturned when we allow for more flexibility in the role of the additive component, as depicted in Figure 2. Assuming a varying share of the additive component over time, product and country partner indeed modifies the decomposition of the trend reduction of transport costs between the one attributable to trade composition effects and the reduction in the “ceteris paribus” transport costs. In both air and vessel transports, we thus find that this last dimension is the main driver of the reduction of international transport costs observed over time, in particular in vessel transport. Complementing the findings of Section 3, these results point out the importance of integrating the additive dimension of international transport costs, here in view

⁴⁶As discussed in Appendix D, our methodology also differs from Hummels (2007) with respect to the weighting scheme used to obtain the evolution of the “ceteris paribus” transport costs over time. Robustness analysis to this point is driven in Section 6.

⁴⁷Unsurprisingly, this stands in accordance with Hummels’ (2007) results, see his Figures 5 (for Air) and 6 (for Vessel)

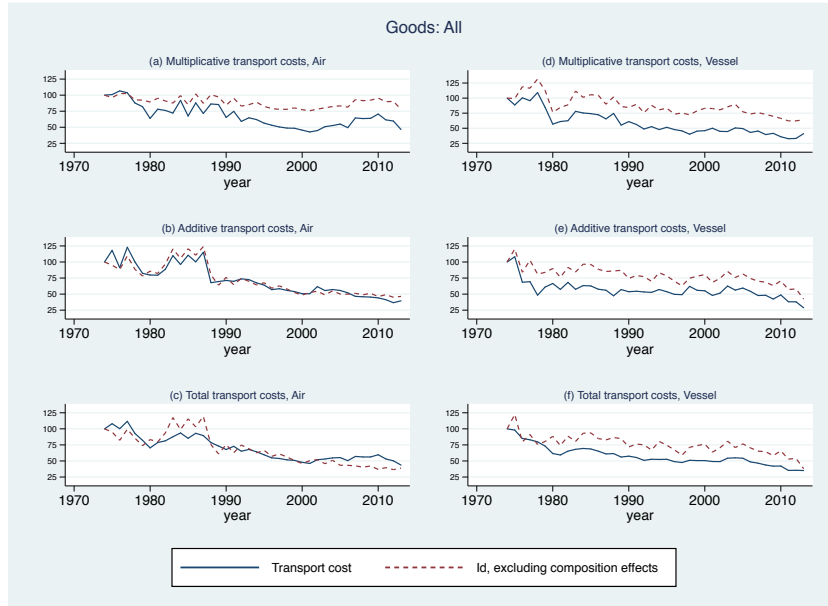

of characterizing their time trends.

6 Time trends in transport costs: Robustness to the weighting scheme

In this section, we provide a robustness test to the weighting scheme implemented to extract the trade composition effects implemented in Section 5. When aggregating the trade cost measure over the product/country (i, k) dimension, Hummels (2007) takes the unweighed average value over the i, k dimension, which implicitly attributes a weight equal to 1 to each flow. We proceed differently, as we weight each flow by its relative value on total trade flows observed in 1974. In this section, our objective is to assess that this difference of treatment is not responsible for the difference of results relative to the role of the trade composition effects, that we rather attribute to the modeling of the additive component.

To this aim, we rebuild the fitted values for each of our transport cost measures (ad-valorem, additive and overall) applying Hummels' s (2007) weighting scheme (ie, taking the unweighed average value over the i, k dimension), which we then express as indices, with the reference value 100 in 1974. The results are reported in Figure 4.

Figure 4: Transport cost time trends: Robustness to the weighting scheme

The comparison of Figure 4 (applying Hummels's (2007) weighting scheme) and Figure 2 (applying our weighing scheme) drives two comments. First, differences do show up, in particular for the multiplicative component of Air transport. This suggests that the weighting scheme is not innocuous in the time trend decomposition exercise. However, Figure 4 also shows that the composition effects have contributed to strengthen the decrease in the “ceteris paribus” transport costs in Air transport (in Figure 4, panel (a), overall transport costs have decreased more that the fitted component), in accordance with

the conclusions drawn from Figure 2, rather than to partially offset as argued by Hummels (2007). Rather than the weighing scheme, this confirms that the functional form and precisely the modeling of the additive component, turns out to be key in understanding the underlying determinants of the overall transport costs time trends, as we pointed out in Section 5.

7 Conclusion

This paper empirically studies the magnitude of additive (or per-kg) costs in international transport costs, by exploiting the differences between the import and the export prices. Using SITC 3 and 4- digit cif-fas unit values taken from the US import database over 1974-2013, we estimate the two components of transport costs, by transport mode (air or ocean). Our results may be summarized in three main findings. First, we provide a quantitative measure of both the additive and the iceberg transport cost. We thus find that additive costs amount to 2.8% of the export price unit values for ocean shipping, and ad-valorem ones 3.2%, as mean values over 1974-2013. These values are respectively equal to 1.8 and 2.5% for air transport. Second, we show that taking additive costs into account improves the fit of the modeling of transport costs. All goodness-of-fit measures point out to this conclusion, which holds for both transport modes and all years considered. Third, we show the importance of integrating the additive component in accounting for the time trend of international transport costs. Allowing for a varying share of additive costs in product/country/time dimension, we obtain that the decrease of international transport costs observed in the data is mostly attributable to a reduction in the *pure* transport costs rather than to trade pattern composition effects. In all three aspects, our results point the importance of the additive component in accounting for international transport costs.

Our results could be extended in two main ways. On the empirical side, one may want to go deeper in the “structural” determinants of trade costs, i.e. identify the respective roles of handling costs, insurance and freight at the root of the gap between export and import prices. On the theoretical side, our results can be used to explore the role of additive costs in shaping international trade flows (in an international trade theory perspective) and in affecting the international transmission of business cycles. This is left for further research.

A Data Appendix

The Customs value is the value of imports as appraised by the U.S. Customs and Border Protection in accordance with the legal requirements of the Tariff Act of 1930, as amended. This value is generally defined as the price actually paid or payable for merchandise when sold for exportation to the United States, excluding U.S. import duties, freight, insurance, and other charges incurred in bringing the merchandise to the United States. The term “price actually paid or payable” means the total payment (whether direct or indirect, and exclusive of any costs, charges, or expenses incurred for transportation, insurance, and related services incident to the international shipment of the merchandise from the country of exportation to the place of importation in the United States) made, or to be made, for imported merchandise by the buyer to, or for the benefit, of the seller. In this respect, the “custom value” corresponds to the *fas* price (“free-alongside” price) delivered by the seller.

The import charges represent the aggregate cost of all freight, insurance, and other charges (excluding U.S. import duties) incurred in bringing the merchandise from alongside the carrier at the port of exportation in the country of exportation and placing it alongside the carrier at the first port of entry in the United States. In the case of overland shipments originating in Canada or Mexico, such costs include freight, insurance, and all other charges, costs and expenses incurred in bringing the merchandise from the point of origin (where the merchandise begins its journey to the United States in Canada or Mexico) to the first port of entry.

The *cif* (cost, insurance, and freight) value represents the landed value of the merchandise at the first port of arrival in the United States. It is computed by adding “Import Charges” to the “Customs Value” (see definitions above) and therefore excludes U.S. import duties.

B Estimation at the 3-digit classification level

B.1 Transport costs estimates: More detailed results

In this section, we report more detailed results for the estimates for international transport costs, by transport mode on a yearly basis, when either additive costs are included in the estimation (Equation (6)) or not (Equation (7)), under our benchmark sectoral classification level (3 digit). Precisely, we complement the results displayed in Table 1 by reporting the estimates of international transport costs for a sample of years over 1974-2013, when the degree of classification retained (s) is at the 3-digit classification level. Table 2 reports the results for Air transport. The results for Ocean transport are displayed in Table 3.

B.2 Assessing the importance of additive transport costs

In this section, we explore the performances of each type of model (with and without additive costs) in fitting the observed *cif-fas* prices gap, in order to deliver a more systematic diagnosis about the importance of additive costs. To do so, we rely on several

Table 2: Air: Transport costs estimates, 3-digits (selected years)

| Year | 1974 | 1980 | 1990 | 2000 | 2010 | 2013 |
|--|-------|-------|-------|-------|-------|-------|
| Model (A) - With only Ad-Valorem TC ($\hat{\tau}^{ice}$, in %) | | | | | | |
| Mean | 6.9 | 5.4 | 5.0 | 3.6 | 4.2 | 3.4 |
| Median | 5.4 | 3.8 | 4.4 | 2.5 | 3.4 | 2.9 |
| Model (B) - With Additive & Ad-Valorem TC | | | | | | |

Notes: TC = Transport Costs. Statistics are obtained weighting each observation by its value in transport (mode-dependent). Additive term expressed in fraction of fas price.

standard measures of fit. The first indicator is through comparing R^2 . However, its use is far from being straightforward when evaluating non-linear estimates.⁴⁸ This drives us to complement the goodness of fit diagnosis with three alternative measures. We provide the Standard Error of Regression (SER), which represents the average distance that the observed values fall from the regression line. The smaller the SER value, the better the quality of fit, as it indicates that the observations are closer to the fitted line. We also report the log-likelihood function, and two measures derived, the Akaike Information Criterion (AIC) and the log-likelihood (LL) ratio test. A decrease in the log-likelihood function points to a better quality-of-fit. However, the likelihood function systematically decreases with the number of parameters included; the AIC criterion allows for correcting this overfitting by including a penalty in the computation of the statistic.⁴⁹ The preferred model is the one with the minimum AIC value. Finally, the log-likelihood ratio test statistic compares systematically the likelihood of the Unrestricted model (UR , including the additive term, i.e. Equation (6)) and the Restricted one (R , i.e. Equation (7)). The null tested is that the two models are statistically equivalent. Results are reported in Tables 4 and 5, for Air and Vessel respectively, at the 3-digit level.

Table 4: Air: Measures of Goodness-of-fit (3 digits)

| Year | 1974 | 1980 | 1990 | 2000 | 2010 | 2013 | Mean stat |

| p-value | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 |

Notes: Model (A) = with only ad-valorem transport costs. Model (B) = with additive & ad-valorem transport costs. SER = Standard Error of regression; AIC = Akaike Information Criterion. R^2 between the log of predicted ratio and the log of the observed ratio. For the LL ratio test, the number of restrictions is equal to the number of parameters estimated, i.e., the number of partner countries plus the number of products. The mean statistics calculated as the average value over all years.

Tables 4 and 5 lead to the same conclusion: The inclusion of the additive term leads to an improvement of the quality of fit, whatever the considered criterion or the transport mode. On average over the whole period, the R^2 doubles when per-kg costs are included for Air, and increases by 50% for Vessel. Similar qualitative conclusions arise from the comparisons of the standard errors of the regression (SER). Regarding the other criteria, improvements allowed by the inclusion of the additive term are roughly of the same ex-

⁴⁸ R^2 is based on the underlying assumption that the adjusted model is a linear one. In a non-linear context, R^2 is strictly speaking inappropriate. However, if the error distribution is approximately normal, a standard metric like R^2 remains informative on the quality of adjustment.

⁴⁹Precisely, the AIC stat is equal to $2 \times \text{number of parameters} - 2 \times \text{Likelihood}$, the number of parameters being given by the number of restrictions.

Table 5: Vessel: Measures of Goodness-of-fit (3 digits)

| Year | 1974 | 1980 | 1990 | 2000 | 2010 | 2013 | Mean stat |

| p-value | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 |

Notes: Model (A) = with only ad-valorem transport costs. Model (B) = with additive & ad-valorem transport costs. SER = Standard Error of regression; AIC = Akaike Information Criterion. R^2 between the log of predicted ratio and the log of the observed ratio. For the LL ratio test, the number of restrictions is equal to the number of parameters estimated, i.e., the number of partner countries plus the number of products. The mean statistics calculated as the average value over all years.

tent across transport modes. Both AIC and Log-Likelihood statistics decrease with the inclusion of the additive term, and the log-likelihood test unambiguously rejects the null of statistical equivalence of the two models. These results holds whatever the considered year.

For comparison purposes, we provide a similar goodness-of-fit exercise at the 4-digit product level (4-digits), reported in in Appendix C, Tables 8 and 9. If anything, the quality of fit appears slightly higher when estimations are based on the 4-digit classification. This is especially true for the model restricting transport cost to their ad-valorem dimension, whatever the transport mode considered. When the additive part is taken into account however, the difference in goodness of fit between the 3- and the 4-digit classification level becomes very small, whatever the considered criterion. In other words, if using a more disaggregated classification unsurprisingly adds some statistical precision, this is not to an extent that would disqualify the use of slightly more aggregated data. Further, the same conclusion established at the 3-digit level regarding the significant role of the additive component in fitting international transport costs emerges at the 4-digit level.

B.3 Variance decomposition exercise

In this section, we provide a variance decomposition exercise on the observed cif-fas price gap. Precisely, we determine the share of the observed variance in the ratio $\ln(\frac{p_{ik}}{p_{ik}} - 1)$ that comes from *i*) the between-product variance (at the 5-digit level, *k*), *ii*) the between-sector variance (at the 3-digit level, *s*). The variance decomposition expression at the product level *k* (5-digit level) is obtained by applying the following formula (by year and transport mode):

$$\underbrace{\sum_{k=1}^K \sum_{i=1}^I (x_{ij} - \bar{x}_g)^2}_{\text{Total variability}} = \underbrace{\sum_k \sum_i (x_{ik} - \bar{x}_k)^2}_{\text{Within-product variability}} + \underbrace{\sum_k (\bar{x}_k - \bar{x}_g)^2}_{\text{Between-product variability}}$$

with x the observed cif-fas price gap and \bar{x}_g , \bar{x}_k average values defined as:

$$\bar{x}_g \equiv \frac{1}{n} \sum_{k=1}^K \sum_{i=1}^I x_{ik}, \quad \bar{x}_k \equiv \frac{1}{K} \sum_{k=1}^K x_{ik}$$

with n the total number of observations, K the total number of products and I the total number of country partners. We apply the same variance decomposition exercise at the sector level, in which case the sector s index (at the 3-digit level) replaces the k index (at the 5-digit level). This gives us an alternative way to ensure the robustness of the estimation results to the degree of classification retained to estimate international transport costs. We also determine the share of the observed variance that can be attributed to the between-country variance, adapting the variance decomposition formula written above accordingly. Results are reported in Figure 5.

Figure 5: Variance decomposition (observed cif-fas price gap)

Two interesting results emerge from Figure 5. First, the share of the cif-fas price gap variance that comes from the variance between products (5-digit level) is of same magnitude of order at the variance between sectors at the 3-digit level. Both account for between 30 and 40% of the total variance in Air transport, depending on the years considered. This is also the case for vessel transport, even if the difference between the between-product variance share and the between-sector share is more pronounced (30% for the between-sector vs 40% for the between-product variance at the beginning of the period). This delivers an indirect robustness check to the degree of classification we have retained to estimate international transport costs. Second, the variance of the cif-fas

price gap that can be attributed to the product (or sector) dimension is much larger than the between-country variance. This holds throughout the period and for both transport modes. This suggests that what primarily matters in international transport costs is mostly attributable to the product *per se*, rather than to the country where it comes from. By extension, one can expect a limited role of distance and other country-related variables as determinants of transport costs.

C Estimation at the 4-digit level

In this section, we report the estimation results when we retain the 4-digit classification level ($s=4$ -digit).

C.1 Transport cost estimates

Tables 6 and 7 report the estimates of both models (with and without additive costs) in Air and Ocean transport respectively.

Table 6: Air: Transport costs estimates, Selected years, 4-digit

| Year | 1974 | 1981 | 1989 | 2001 | 2009 | 2013 |
|--|-------|-------|-------|-------|-------|-------|
| Model (A) - With only Ad-Valorem TC ($\hat{\tau}^{ice}$, in %) | | | | | | |
| Mean | 6.6 | 5.8 | 5.2 | 3.3 | 3.7 | 3.2 |
| Median | 5.2 | 4.4 | 4.1 | 2.1 | 2.7 | 2.6 |
| Model (B) - With Additive & Ad-Valorem TC | | | | | | |
| <i>Ad-valorem term ($\hat{\tau}^{adv}$, in %)</i> | | | | | | |
| Mean | 3.5 | 2.6 | 3.1 | 1.5 | 2.1 | 1.6 |

C.2 Goodness-of-fit tests at the 4-digit level

We now report the goodness-of-fit exercise (conducted by transport mode) at the 4-digit product classification level (for the selected years). The results are reported in Tables 8 (for Air) and 9 (for Vessel).

D Eliminating the composition effects: More details

In this section, we explain in more details the method employed to eliminate the country- and product- dimensions of the estimated transport cost.

Table 7: Vessel: Transport costs estimates, Selected years, 4-digit

| Year | 1974 | 1981 | 1989 | 2001 | 2009 | 2013 |
|--|-------|-------|-------|-------|-------|-------|

D.1 More on our methodology

D.1.1 Additive and ad-valorem transport costs: Excluding the composition effects

In this section, we detail our methodology to extract the time trend in the “ceteris paribus” (or fitted) transport cost component, for each the ad-valorem and the additive component.

For the ad-valorem component Consider first the multiplicative transport cost component. Rewriting Equation (10) by taking the exponential, we get:

$$\hat{\tau}_{ikt} = \exp \left(\delta + \sum_{i \neq \text{AFG}} \alpha_i \cdot \mathbb{1}_i + \sum_{k \neq 011} \beta_k \cdot \mathbb{1}_k \right) \cdot \exp \left(\sum_{t \neq 1974} \gamma_t \cdot \mathbb{1}_t \right) \cdot \exp(\epsilon_{ikt})$$

Based on this equation, we deduce after estimation that:

$$\begin{aligned} \text{For the year 1974} \quad & \hat{\tau}_{is74} = \exp(\delta + \alpha_i + \beta_s), \\ \text{For any year } t > 1974 \quad & \hat{\tau}_{ist} = \exp(\delta + \alpha_i + \beta_s) \times \exp(\gamma_t) \end{aligned}$$

From this, we obtain the following recursive link: $\hat{\tau}_{ist} = \hat{\tau}_{is74} \exp(\gamma_t)$. Given that $\tau > 1$, we can rewrite to get the percentage change between year 1974 and any year $t > 1974$:

$$\Gamma_{ist} = 100 \cdot \frac{\hat{\tau}_{ist} - 1}{\hat{\tau}_{is74} - 1} = 100 \cdot \frac{\hat{\tau}_{is74} \exp(\gamma_t) - 1}{\hat{\tau}_{is74} - 1}$$

As such, the index of transport costs in year t (relative to the reference year 1974)

Γ_{ist} only depends on the cost observed in 1974 and the time trend. At this stage though, it remains specific to a product-origin country pair. Next step is to build the index Γ_t^{adv} such that:

$$\Gamma_t^{adv} = 100 \frac{\bar{\tau}_{1974} \cdot \exp(\gamma_t) - 1}{\bar{\tau}_{1974} - 1} \quad (14)$$

that is, Equation (12) with $\bar{\tau}_{1974} = \exp(\delta + \sum_i \alpha_i + \sum_k \beta_k)$ the mean (ad-valorem) transport cost in 1974.

For the additive component After estimating Equation (11), we can re-build the additive component according to:

$$\begin{aligned} \text{For the year 1974} \quad & \hat{t}_{is74} = \delta + \alpha_i + \beta_s, \\ \text{For any year } t > 1974 \quad & \hat{t}_{ist} = (\delta + \alpha_i + \beta_s) \cdot \exp(\gamma_t) \end{aligned}$$

From this, we deduce the recursive link: $\hat{t}_{ist} = \hat{t}_{is74} \times \exp(\gamma_t)$. Given the constraint $t > 0$, we then obtain the percentage change from 1974 from:

$$\Gamma_{ist}^{add} = 100 \frac{\hat{t}_{ist}}{\hat{t}_{ik74}} = 100 \exp(\gamma_t) \quad (15)$$

Note that it is independent of the product-origin country pair, we can thus rewrite the time-trend series for the additive transport cost component as:

$$\Gamma_t^{add} = 100 \exp(\gamma_t) \quad (16)$$

Obtaining the unfitted measures It consists in expressing the unfitted transport cost component as an index, with reference value 100 in 1974, starting from the estimated values previously obtained ($\hat{\tau}_t$, \hat{t}_t , for each year t from 1974 to 2013). That is, we apply the simple formula to get the following indices, for the ad-valorem and the additive cost components respectively:

$$\Gamma_t^{adv,raw} = 100 \times \frac{\hat{\tau}_t}{\hat{\tau}_{1974}}, \quad \Gamma_t^{add,raw} = 100 \times \frac{\hat{t}_t}{\hat{t}_{1974}}$$

D.1.2 For the total cost measure

We also build a measure of the “overall” transport costs, that agglomerates our estimates of the two additive and iceberg components. We construct this measure (by transport mode) on both the unfitted series and the “pure” transport cost series (composition effects excluded). Even if obeying to the same logic, we proceed slightly differently for the unfitted and the fitted measures though, as we now explain.

For the unfitted measure, based on Equation (2), we build for each transport mode, the “overall” transport cost as:

$$\hat{t}C_t^{raw} = \hat{\tau}_t^{adv} - 1 + \hat{t}_t$$

where $\hat{\tau}_t^{adv}$ and \hat{t}_t have been estimated (by year) as explained in Section 2, $\hat{\tau}_t^{adv} - 1$ measuring the ad-valorem transport cost component and \hat{t}_t the additive component, both expressed in percentage of the fas price. For sake of comparison, we transform this “overall” transport cost in an index with basis year 1974, applying a similar formula as above (by transport mode):

$$\Gamma_t^{tc,raw} = 100 \frac{\hat{tc}_t^{raw} - 1}{\hat{tc}_{1974}^{raw} - 1}$$

We apply the same logic to construct the fitted measure of total transport cost (i.e., composition effect excluded), with a first step that consists in getting the fitted measures of each transport cost component in value (rather than as an index). For the ad-valorem component, this can be obtained starting from Equation (14), rewritten to get:

$$\hat{\tau}_t^{cp,adv} = \frac{\Gamma_t^{adv} (\bar{\tau}_{1974} - 1)}{100} + 1$$

with $\hat{\tau}_t^{cp,adv} \equiv \bar{\tau}_{1974} \cdot \exp(\gamma_t)$ the yearly value of the *ceteris paribus* (fitted) ad-valorem cost. A similar reasoning starting from Equation (16) gives the fitted value for the additive cost component as:

$$\hat{t}_t^{cp} = \frac{\Gamma_t^{add}}{100}$$

with $\hat{t}_t^{cp} \equiv \exp(\gamma_t)$ the yearly value of the *ceteris paribus* (fitted) additive cost.

We then deduce the fitted value of the overall cost according to:

$$\hat{tc}_t^{cp} = \hat{\tau}_t^{cp,adv} + \hat{t}_t^{cp}$$

Last, we transform this (fitted) “overall” transport cost in an index with basis year 1974, applying a similar formula as above (by transport mode):

$$\Gamma_t^{tc} = 100 \frac{\hat{tc}_t^{cp} - 1}{\hat{tc}_{1974}^{cp} - 1}$$

This finally leaves us with six time series, all built as indices with the reference value 100 in 1974: Three time series for the unfitted transport costs measures $\{\Gamma_t^{add,raw}, \Gamma_t^{adv,raw}, \Gamma_t^{tc,raw}\}$ (additive, ad-valorem and overall resp.), and three series for the fitted values $\{\Gamma_t^{add}, \Gamma_t^{adv}, \Gamma_t^{tc}\}$ (additive, ad-valorem and overall respectively).

D.2 Comparing with Hummels (2007)

In this section, we investigate the difference of results with Hummels (2007) regarding the importance of the composition effects in characterizing the time trends of international transport costs. In order to do so, we start from the empirical specification implemented by Hummels (2007) (also making use of Hummels’ Stata codes provided on his webpage⁵⁰), to better identify the precise points of difference between our estimation strategies.

⁵⁰<http://www.krannert.purdue.edu/faculty/hummelsd/research/jep-transport-cost-data.php>

Let us start from Hummels' (2007) quotation (p. 146) according to which (for air), the “*unadjusted measure of ad valorem air shipping costs [is] the aggregate expenditures on air shipping divided by the value of airborne imports*”. From this, we get the “raw” ad-valorem measure of transport costs as the ratio between the imported total value and the exported total value $((p_{ikt} - \tilde{p}_{ikt})q_{ikt}/\tilde{p}_{ikt}q_{ikt})$, the mean yearly value being obtained by weighting each flow by its value in total trade flows (ie, yielding the observed aggregate value of τ_t for air).

Consider now the “fitted ad-valorem rate”. Hummels (2007) uses “*a regression in which the dependent variable is the ad-valorem air freight cost in logs for commodity k shipped from exporter i ⁵¹ at time t . The independent variables include a separate intercept for each exporter-commodity shipped, the weight/value ratio in logs for each shipment, and year dummy variables*”. With the value of the shipment equal to $\tilde{p}_{ikt}q_{ikt}$, and denoting the air freight cost as TC_{ikt} , we can formulate the above sentence according to the following equation (suppressing the transport mode index to alleviate notation):

$$\begin{aligned} \ln TC_{ikt} &= \delta + \beta \ln \frac{q_{ikt}}{\tilde{p}_{ikt}q_{ikt}} + \sum_{i,k} \alpha_{ik} \cdot \mathbb{1}_{ik} + \sum_t \gamma_t \cdot \mathbb{1}_t + \epsilon_{ikt} \\ \Leftrightarrow \quad \ln TC_{ikt} &= \delta + \beta \ln \frac{1}{\tilde{p}_{ikt}} + \sum_{i,k} \alpha_{ik} \cdot \mathbb{1}_{ik} + \sum_t \gamma_t \cdot \mathbb{1}_t + \epsilon_{ikt} \end{aligned} \quad (17)$$

where TC_{ikt} is measured by the ratio between (air) charges, i.e. $(p_{ikt} - \tilde{p}_{ikt})q_{ikt}^{fas}$ and the value of the shipment, i.e. $\tilde{p}_{ikt}q_{ikt}^{fas}$, or equivalently : $TC_{ikt} = \frac{p_{ikt} - \tilde{p}_{ikt}}{\tilde{p}_{ikt}}$.

After estimating Equation (17), Hummels (2007) uses the predicted value of the regression, denoted \widehat{TC}_{ikt} , to obtain the unweighed average in the product/origin country dimension i, k , that is \widehat{TC}_t , to be compared to the unfitted ad-valorem rate TC_t (by transport mode).

What are the main differences with our estimation strategy? Five points may be underlined. First, Hummels (2007) obtains the fitted ad-valorem rate in one step (considering the observed export-import price gap on the left-hand side of Equation (17)), while we use our two-step approach to extract the fitted transport cost (ie, composition effect excluded) from the (already estimated) unfitted rate. However, this is a slight difference, as in both cases it ultimately amounts taking the predicted value of Equation (17) (which eliminates the changes specific to the origin country/product/year triplet).

A second minor difference is that we separate the country-product fixed effects ($\sum_{i,k} \alpha_{ik} \cdot \mathbb{1}_{ik}$ in Equation (17)) in two separate components (origin country and product dimensions). As discussed in Section 6, this is constrained by the number of fixed effects to estimate. However, we do not view this as the major cause of difference between our two methods, as it can be inferred from the robustness analysis on this point in Section 6.

Third, in contrast to us, Hummels (2007) does not purge its measure of the fitted ad-

⁵¹To be consistent with our notations, we change the country subscript from j (Hummels' (2007) terminology) to i (our terminology).

valorem rate by the country-sector fixed effects. This is not likely to make a substantial difference though, as these fixed effects are by nature constant over time. Accordingly, they only play as a scale effect as the estimate is in log. Fourth, we differ in the weighting scheme retained to obtain the yearly value of the fitted transport cost (in the terms of Hummels' (2007) method, the switch from \widehat{TC}_{ikt} to \widehat{TC}_t , Equations (12) and (13) in our case). Hummels (2007) takes the unweighed average value over the i, k dimension, which implicitly attributes a weight equal to 1 to each flow. We proceed differently, as we weight each flow by its relative value on total trade flows observed in 1974. This choice is made for two reasons. First, this weighting scheme does not overweight the small flows in value. Second, considering the 1974 weighting scheme makes sense as starting point of our time trend analysis. However, we ensure that our results are not sensitive to an alternative weighting scheme, by building the average fitted transport costs rate as in Hummels (2007), as reported in Section 6.

One last difference remains to be commented, which relies on the way the additive component of international transport costs is treated. As we show below, it turns out to be key in accounting for the difference of results with Hummels (2007). Coming back to Equation (17), it can be shown that it encompasses the two extreme cases of only ad-valorem costs ($\beta = 0$) and only additive costs ($\beta = 1$), as also pointed out in Hummels and Skiba (2004). To see it clearly, rewrite Equation (17) in a simpler form as:

$$\ln TC_{ikt} \equiv \ln \left(\frac{p_{ikt} - \tilde{p}_{ikt}}{\tilde{p}_{ikt}} \right) = \Delta_{ikt} - \beta \ln \tilde{p}_{ikt}$$

with $\Delta_{ikt} \equiv \sum_{i,k} \alpha_{ik} \cdot \mathbb{1}_{ik} + \sum_t \gamma_t \cdot \mathbb{1}_t$ agglomerates the various fixed effects for reading clarity.

Under the first polar case with $\beta = 1$, it becomes:

$$\begin{aligned} \ln \left(\frac{p_{ikt} - \tilde{p}_{ikt}}{\tilde{p}_{ikt}} \right) &= \Delta_{ikt} - \ln \tilde{p}_{ikt} \\ \Leftrightarrow \ln(p_{ikt} - \tilde{p}_{ikt}) &= \Delta_{ikt} \end{aligned}$$

Equivalently, we can write:

$$\begin{aligned} p_{ikt} &= \tilde{p}_{ikt} + \exp(\Delta_{ikt}) \\ \Leftrightarrow p_{ikt} &= \tilde{p}_{ikt} + t_{ikt} \end{aligned}$$

with t_{ikt} appropriately defined. This exactly corresponds to the case of additive costs only.

In the second polar case with $\beta = 0$, Equation (17) becomes:

$$\begin{aligned} & \ln \left(\frac{p_{ikt} - \tilde{p}_{ikt}}{\tilde{p}_{ikt}} \right) = \Delta_{ikt} \\ \Leftrightarrow & \ln \left(\frac{p_{ikt}}{\tilde{p}_{ikt}} - 1 \right) = \Delta_{ikt} \\ \Leftrightarrow & \frac{p_{ikt}}{\tilde{p}_{ikt}} = \exp(\Delta_{ikt}) + 1 \end{aligned}$$

that is,

$$p_{ikt} = \tau_{ikt} \tilde{p}_{ikt}$$

with τ_{ikt} appropriately defined. This exactly corresponds to the case of ad-valorem transport costs only.

As noted by Hummels and Skiba (2004), $0 < \beta < 1$ represents the elasticity of freight costs to the export prices, increasing with the relative weight of the additive component in international transport costs. By estimating Equation (17) with a constant β , Hummels (2007) assumes that the share of additive costs does not vary over time, country partner or product. This is an important difference with our method, as we measure transport costs by explicitly allowing for an additive component that varies in the three dimensions (ie, somehow allowing for a varying β across time, country partner and product). To establish this point clearly, we replicate the method adopted by Hummels (2007) exposed above on our database (which is the same as his until 2004). The results are reported in Figure 3.
