A. Three models: Comparison

The paper compares the empirical performances of two models: one with only advalorem costs (Model (A)) and one with where both ad-valorem and additive costs (Model (B)). In the interest of comprehensiveness, this appendix looks at a model with only additive costs (Model (C)). The estimated equation is: $\ln\left(\frac{p_{ik}}{\tilde{p}_{ik}}-1\right) = \ln\left(\frac{t_i+t_s(k)}{\tilde{p}_{ik}}\right) + \epsilon_{ik}^{add}$. We first compare estimates of the transport costs components under the three models. In a second step, we report quality of fit tests for the three models.

A.1. Estimation results

In this section, we report the estimation results of the three models. We also report the estimation results for Model (C), where only additive costs are modeled. Table A.1 reports the results for air transport, Table A.2 for vessel transport.

Table A.1: Estimation results of the three models (Air, 3-digit level)

Results for Models (A) (ad-valorem costs only) and (B) (both ad-valorem and additive costs) are identical to those reported in the paper. Somewhat unsurprisingly, the estimated size of transport costs under Model (C) is of same order of magnitude as in Models (A) and (B). We also observe a downward trend of transport costs over time, in particular since 1980.

A.2. Quality of fit diagnostic tests

0.09

0.08

0.08

To go further into characterizing the empirical relevance of the model with aditive costs only (Model (C)), we compare quality of fit diagnostic tests in this section. Table A.3 reports the results for air transport, and Table A.4 those for vessel transport. In both tables, we report the values of the R^2 , the Standard Error of Regression (SER), the AIC criterion and the log-likelihood (LL) value. We also report the value of the log-likelihood ratio that tests the quality of fit of the global model (Model (B)) compared to the other two models.

The model with additive costs only (Model (C)) is consistently dominated (in terms of quality of fit properties) by the model with multiplicative costs only (Model (A)), which is itself consistently dominated by the complete model (Model (B)), whatever the type of diagnostic test considered. That justify our choice to disregard Model (C) in the main text.

B. Transport Cost Estimates: Yearly Detailed Results

In this section, we complement Table 1 of the main text by reporting the year-to-year results of the estimation driven at the 3-digit classification level. Table B.1 reports the results for each year over 1974-2013 for air transport; Table B.2 reports similar results for vessel. In both cases, we report the estimated values of the transport costs (weighed mean and median) when only ad-valorem costs are modeled (Model (A)) and when both additive and ad-valorem costs are modeled (Model (B)).

As mentioned in the paper, the estimates for air transport costs in 1989 show a surprisingly high value for the additive component (the additive cost is estimated to amount to 4.6% of the export price, whereas it amounts to 2.5% on average between 1974 and 1988, and to 1.7% over the following decade 1990-2000). This can be attributed to the presence of outliers in the distribution of the additive costs estimates. The maximum value for \hat{t}/\tilde{p} is 10,000% in 1989, whereas it amounts to 1,690% on average over 1974-1988 and to 1,500% on average over 1990-2000. Accordingly, in the paper we discard this year 1989 when we report the average values over the period of the transport costs estimates in air transport.

Still, this does not make much difference. When 1989 is included, the weighed mean transport cost value amounts to 1.9% for the ad-valorem component, vs 1.8% when 1989 is excluded. The weighed median value is left unchanged at 2.9% whether 1989 is included or not.

C. Eliminating the composition effects: Primary vs. Manufacturing sector

In this section, we refine the characterization of the evolution of international transport costs by distinguishing primary goods trade flows and and manufactured goods trade flows. The evolution in transport costs over time, by transport mode (overall transport costs and composition effects excluded) are reported in Figure C.1 for the manufacturing sector, and in Figure C.2 for the primary goods. For easing comparison, we also report the results obtained on the whole range of trade flows (i.e., Figure 2 of the paper), in Figure C.3.

The classification retained to categorize trade flows follows the UNCTAD classification (on STIC Revision 3)⁴. Are considered as "primary goods" all flows recorded as "Food and live animals" (First digit "0" in the SITC Classification), "Beverages and tobacco" (First digit "1"), "Crude materials, inedible, except fuels" (First digit "2"), "Mineral fuels, lubricants and related materials" (First digit "3"), "Animal and vegetable oils, fats and waxes" (First digit "4"), "Pearls, precious & semi-precious stones" (Classified "667" in the SITC Classification) and "Non-ferrous metals" (classified "68" in the SITC Classification).

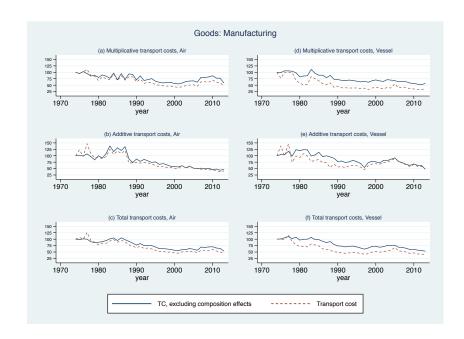

Figure C.1: Transport costs (with and without composition effects), Manufacturing

As reported in Figures C.1 and C.2, the "raw" transport costs and the unfitted transport costs, in the red dashed line plain have regularly declined over the period in both sectors, by roughly the same order of magnitude (50% in air, 60% in vessel). However the role of trade composition effects in accounting for this trend pattern differs depending on the sector.

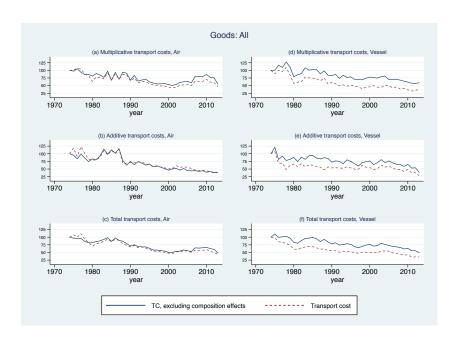

Figure C.1 (for manufactures) reports a very similar time trend decomposition than what is obtained on the whole range of goods (Figure C.3). In air transport, most of the decrease can be imputed to the reduction of "ceteris paribus" transport costs (the blue continuous line), trade composition effects playing virtually no role (Figure C.1, left-hand panels (a), (b) and (c)). Trade composition effects matter more in vessel transport (Figure C.1,

⁴See "UNCTAD product groupings and composition (SITC Rev. 3)" in http://unctadstat.unctad.org/EN/Classifications.html, accessed Septembre 2018

Figure C.2: Transport costs (with and without composition effects), Primary goods

Figure C.3: Transport costs (with and without composition effects)

right-hand panels (d), (e) and (f)), primarily in the ad-valorem component. As for the whole range of flows, the 60% decrease in the unfitted transport costs in vessel can de decomposed in a 50% decrease in the "ceteris paribus" transport costs (fitted), the 10% remaining to trade composition effects.

The situation is is strikingly for primary goods only. In this case, it is in air transport that composition effects do matter (Figure C.2, left-hand panels (a), (b) and (c)), while we observe not much role for them in vessel transport (Figure C.2, left-hand panels (d), (e) and (f)). Furthermore, in air transport, composition effects matter by partially offsetting the decrease in the "ceteris paribus" transport costs (ie, implying a reduction in the "raw" transport costs over time much less pronounced than the fitted transport cost measures).

One explanation for the similarity between the results for the manufacturing goods trade and for total trade can be found in the share of primary goods in total flows as reported in Figure C.4. In air transport, the share of primary goods in the total value of US imports is very small, around 10%. Primary goods make a higher proportion of trade flows in vessel transport, especially over 1974-1982 (between 40% and 60%). On the following sub-period though, their share has fallen to 20-30%. Given the modest proportion of primary goods in total import flows of the US economy compared to the manufactured sector, it is hence not surprising that the diagnosis made about the time trend of transport costs when all types of flows are considered is driven by the trend patterns that occur within the manufacturing sector.

Figure C.4: Share of primary goods in the value of total US imports
